ABSTRACT

Climate change will impact current and future generations in different regions very differently. This paper develops the first large-scale, annually calibrated, multi-region, overlapping generations model of climate change and carbon policy. It features region-specific temperature and damage functions with the phased impact of emissions on global and regional temperature calibrated to the latest scientific evidence. Absent policy, climate change may, under high-damage scenarios, dramatically reduce GDP in most regions, with India, Brazil, and the South Asian Pacific suffering long-term catastrophic damages. Carbon taxation, coupled with region- and generation-specific transfers, can both correct the carbon externality and raise the welfare of all current and future agents across all regions by 4.3 percent. The impact on the use and duration of fossil fuels is dramatic as is the reduction in the path of global emissions. However, achieving completely uniform welfare gains leaves future generations in particular regions facing exceptionally high compensatory payments. Fortunately, a carbon tax-cum redistribution policy that limits this burden for any generation in any region to less than 10 percent, measured on a consumption-equivalent basis, can deliver a 4.0 percent or higher welfare gain for all peoplekind — present and future. However, carbon taxes set through time, at carbon's marginal social cost, do far too little to mitigate climate change unless all major emitters, particularly China, adopt them and do so immediately.

1. Introduction

Our problems are man-made; therefore, they can be solved by man. These inspiring words by President Kennedy apply in full measure to anthropogenic climate change with its massive projected damages — arguably humankind’s worst externality. This paper develops a large-scale, multi-region, overlapping generations (OLG) model to study climate change’s cumulative damage to global and regional output as well as carbon taxation’s mitigation potential. Our model features 18 regions inhabited by 80 overlapping, selfish generations. Each region’s demographic conditions and projections are closely calibrated to UN data. Output is produced with capital, labor, and a time-varying combination of dirty and clean energy. Dirty energy comprises oil, gas, and coal, each of whose extraction is subject to increasing costs. Clean energy is produced with capital, labor, and a fixed factor that proxies for regional limits on green-energy production. Our equations connect carbon emissions to atmospheric carbon concentration and, thereby, mean global temperature in accordance with the latest climate science and projections.

Our focal carbon policy is not just Pareto improving. It is uniform welfare improving (UWI), indeed, the policy that delivers the highest uniform welfare gain to all cohorts no matter their year or place of birth. We implement this policy for a range of damage functions, but focus on a worst-case scenario. We view the worst case as particularly salient since our deterministic model ignores particularly damaging climate shocks. For our high-damage calibration, an initial \$87.5 carbon tax rising annually at a 1.4 percent coupled with appropriate cohort- and region-specific transfers limits global damages in 2100 by 38 percent. Hence, rather than experiencing a 14 percent drop in global output by 2100, compared to its level absent climate change, global output is only about 9 percent smaller. For India, the hardest hit region, our optimal UWI carbon tax limits the percentage decline in end-of-century output from 38.5 percent to 26.2 percent. For the U.S., the reduction in 2100 GDP is 13.9 percent without the UWI policy and 8.0 percent with it. China’s respective values are 13.7 percent without policy and 7.8 percent with policy. For Canada, which benefits from climate change, climate change will raise GDP in 2100 by 2.5 percent. The UWI policy reduces Canada’s 2100 GDP by 0.6 percent relative to its no climate-change level. In short, absent policy, climate change will, in general, materially undermine economic growth, but do so differentially by region. Yet, carbon taxation, coupled with the appropriate interregional and intergenerational redistribution, can substantially limit the damage while making everyone, across space and time, equally better off.

Background. As with other externalities, climate change reflects market failure, i.e., no cross-region, let alone cross-generation markets for agents to buy or sell abatement. That is the downside. The upside is that correcting the externality permits a continuum of Pareto improvements — efficiency gains that can be allocated to all or some segment of humankind. Identifying the Pareto frontier is a standard operating procedure in analyzing externality problems. It dates to [Pigou \(1920\)](#)’s path-breaking work. However, starting with [Nordhaus \(1979\)](#), climate-change modelers have posited a social planner for the entire planet, with no concern with the status-quo (i.e., “business as usual” (BAU)) welfare distribution and, consequently, no inherent interest in Pareto improvements. This framework begs the question of which social planner with which degree of intergenerational altruism, as captured by the planner’s time preference rate, to invoke.

Much of the more recent optimal carbon tax literature (see, e.g., [Golosov et al. \(2014\)](#)) emulates the social-planner framework by positing infinitely-lived dynasties. Each dynasty comprises altruistically linked agents with typically one such agent alive at a point in time, hence, the nickname *single-agent model*. As in the planner setup, the single-agent approach considers a single-time preference rate. Doing otherwise would endow the most altruistic dynasty with the highest saving rate and eventuate in its holding all of the economy’s wealth. The single-agent model has another major theoretical drawback. Inter-marriage across any two dynasties links the two dynasties altruistically and, given even a very small rate of inter-marriage, links the entire planet altruistically. This issue was first pointed out by [Kotlikoff \(1983\)](#) and then studied in detail by [Bernheim and Bagwell \(1988\)](#). However, the most important reason for questioning the single-agent approach is the abundant evidence, at least in the US, rejecting operative intergenerational altruism — evidence that includes [Abel and Kotlikoff \(1994\)](#), [Altonji et al. \(1992\)](#), [Hayashi et al. \(1996\)](#), [Gokhale et al. \(1996\)](#), and [Altonji et al. \(1997\)](#).

Modeling Choice. [Kotlikoff et al. \(2021\)](#) introduced the concept of a UWI carbon tax in an OLG model, albeit with a single region. Developing, as we do here, a regional model raises major modeling, methodological, computational, and calibration challenges. However, doing so makes it possible to consider ten critical aspects of climate policy.

First, some regions benefit from climate change. Second, given non-linearities in climate damages, one needs to disaggregate regionally to accurately calculate the optimal UWI global carbon tax and the generation- and region-specific net transfers needed to implement Pareto improvements. Third, the magnitude and duration of fossil fuel usage differs according to region. Fourth, different regions may adopt different carbon policies. Fifth, changes in the course of GDP due to carbon policy will differ by region, which, in turn, will impact global emissions, which, in turn, will impact region-specific GDP paths. Consequently, disaggregation presents a more multifaceted simultaneity challenge for calculating optimal carbon policy. Sixth, region-specific generations that are slated to suffer the most from climate change will, under UWI policy, need to pay the highest taxes to compensate for their out-sized climate gains. Collecting such taxes raises questions of compliance and whether limiting compensatory taxation by some will come at a major loss to others. Seventh, certain regions may not agree to tax carbon. Consequently, a regional model is needed to understand what welfare gains subsets of regions can achieve on their own. Eighth, disaggregating by region lets one explore mechanisms to promote international carbon cooperation. Ninth is the need to develop an algorithm to compute global intertemporal Pareto policies that accommodate region-specific compensation. The tenth is to understand how policy delay limits welfare gains in a realistic multi-region setting.

Our model features three goods: (i) output, which can be consumed or invested (used as capital), (ii) clean energy, and (iii) dirty energy. Output is produced with capital, labor, and energy, be it clean or dirty. Clean energy is produced with capital, labor, and land. Each region’s land is in fixed supply, which proxies for region-specific physical limits on generating clean energy. This input

fixity ensures that clean energy is always produced, including in the early stages of the transition when its technology is limited. As for dirty energy, its production is, as indicated, based on the increasingly costly extraction of fossil fuels. Since our model is deterministic and agents are indifferent between holding particular assets, we treat dirty energy companies as globally owned.

Under BAU, that is, no policy, our assumed technological advances in clean energy bring an end to dirty energy's use at region-specific dates. Regions with limited initial clean-energy use have, per our calibration, low initial clean-energy productivity. Consequently, they take longer to wean themselves off fossil fuels. Thus, under BAU, Sub-Saharan Africa will use dirty energy through the end of the next century, whereas the US will stop much sooner. Unfortunately, even though clean energy's productivity growth brings an end under BAU to carbon emissions, the regional carbon end dates are sufficiently distant to permit dirty energy to wreak long-lasting, significant damages. Moreover, the worst damage arises in regions that house the vast majority of the world's current and future populations.

As indicated, our model's UWI policy has two components. First, it taxes carbon emissions at time-varying rates equal to year t 's social cost of carbon (SCC) – the present value of the future global cost of an extra current ton of emissions produced in t .¹ Second, it lump-sum redistributes (compensates) on a generation- and region-specific basis to ensure that all cohorts in all regions experience an identical welfare gain. Given that we are pricing the externality correctly at each point in time, our algorithm delivers the maximum efficiency gains available. In addition to studying the UWI carbon tax policy, which shares all efficiency gains uniformly with all generations across all regions, we entertain UWIF and UWIL policies. The former allocates all efficiency gains solely to future generations. The latter refers to limiting (hence the letter L in UWIL) any generation's net tax to 10 percent of their lifetime consumption.

As for carbon tax revenues, they are lump-sum rebated to dirty energy producers on a period-by-period basis.² As pointed out by [Goulder \(1995\)](#), carbon revenues could be used to reduce other distortions, delivering a “double dividend” and, thus, a higher UWI gain than that computed here.

Who pays (measured as a share of lifetime consumption) the most in compensatory net taxes? Clearly, it is future generations in regions that gain the most from a cooler planet. However, their tax payments are worth the price, leaving them better off to the same percentage degree as all current and future generations in all other regions. How can the policy's redistribution be implemented in practice? An international authority, such as the International Monetary Fund (IMF), could issue green bonds to initially make net transfers and subsequently collect taxes to service the debt.

Our study builds what we believe is the first large-scale OLG integrated assessment model (IAM) with region-specific emissions and damages. As in [Krusell and Smith \(2022\)](#) and several other recent studies, our model determines region-specific temperatures – required to derive region-specific damages – based on a climate-science technique called “pattern scaling”. The latter method can be used to compute the local temperature at grid resolutions as fine as 1-degree latitude by 1-degree longitude, given the global average temperature.³ Our study also handles key feedbacks, including the relationship between global and region-specific temperatures, the impact of region-specific temperatures on region-specific damages, the impact of region-specific damages on region-specific production, the impact of changing region-specific production on region-specific emissions, and the sum of regional emissions determining global emissions and, thus, global temperature. In determining region-specific damages, we rely on [Krusell and Smith \(2022\)](#)'s damage function (albeit based on our calibration), which admits negative as well as positive damages while delivering approximately the same aggregate damages as the DICE 2016 (henceforth, simply DICE) model ([Nordhaus, 2017](#)). Finally, we use [Folini et al. \(2024\)](#)'s recent study that employs state-of-the-art climate modeling to re-calibrate Nordhaus' DICE functions governing the relationships between global emissions, carbon concentration, and global mean temperature.

Preview of Findings. In our high-damage baseline scenario, the increase in the planet's mean surface temperature through 2100, absent policy, is approximately 3.1 degrees Celsius. This is moderately good news for Canada and Russia, whose GDP levels in 2100 are 2.5 percent and 3.6 percent higher, respectively, compared with no climate change. However, the remaining 16 regions suffer, with India, the South Asian Pacific, Sub-Saharan Africa, the Middle East and North Africa being hit the worst. Relative to a world with no carbon-based damage, climate change lowers their 2100 GDP levels by 38.6, 33.4, 33.0, and 30.9 percent, respectively. As for global GDP, its 2100 value is reduced by 14.7 percent. In our BAU scenario, dirty energy lasts through 2217 years. In contrast, optimal UWI policy ends all dirty energy usage by 2103 and dramatically reduces cumulative (2017 through fossil fuel's end date) oil, gas, and coal consumption by 84.4 percent, 86.2 percent, and 98.1 percent, respectively. These major impacts limit the rise in the global mean surface temperature to 2.1 degrees Celsius. Moreover, the peak global GDP loss declines from 16.7 percent to 9.3 percent. Peak regional damages now range from 0.5 percent to 27.8 percent of GDP compared with the range from 2.1 percent to 43.9 under BAU. The striking messages here are both encouraging – global carbon taxation can significantly mitigate losses from climate change – and discouraging – atmospheric carbon concentration is already so high that the optimal UWI carbon tax policy can only limit peak global damages by 44.3 percent.

How large is the optimal UWI gain? It is 4.3 percent, measured as a consumption compensating variation. Thus, implementing UWI policy is equivalent to increasing the annual consumption of each cohort, whether already born or yet to be born, by 4.3 percent under BAU. Implementing UWI policy requires substantial inter-generational and inter-regional net transfers. The largest positive net transfers, around 15 percent of annual and, thus, lifetime consumption, are made to current and near-term generations in three

¹ Taxing fossil fuel extraction rather than fossil fuel usage, i.e., operating on the other side of the market, would generate identical results, the equilibrium is unchanged.

² Rebating carbon revenues to dirty energy suppliers does not alter outcomes. For example, were we to rebate carbon revenues on a global per capita basis, the UWI region- and generation-specific net transfers would adjust to maintain the original equilibrium.

³ See, e.g., [Lynch et al. \(2017\)](#), [Kravitz et al. \(2017\)](#), and references therein.

regions, namely, Russia, Former Soviet Central Asia, and Eastern Europe. These regions experience particularly large increases in energy costs, not due to their ownership or production of fossil fuels (recall, fossil fuels are a global asset), but due to their heavy use of fossil fuels in production.

In contrast, Indian generations born after the year 2200 face the largest net negative transfers, i.e., positive net taxes — roughly 40 percent of lifetime consumption. This reflects the huge benefit future Indians accrue from carbon taxation. Generations born in the long run in the Middle East, Latin America excluding Mexico and Brazil, Sub-Saharan Africa, Brazil, and the South Asian Pacific face net taxes equal to roughly 30 percent of their lifetime consumption. As for those born in the long run in the US, Japan/South Korea/Hong Kong, China, South Africa, Australia, and New Zealand, the net tax is equivalent to almost 15 percent of lifetime consumption.

The time consistency problem raised by the UWI solution is apparent. Once the danger of climate change has been reduced, policy beneficiaries may choose not to service outstanding green bonds or refuse to do so beyond a limit. One response is to consider UWIF policy, which limits the UWI gain to future generations, leaving, as mentioned, current generations at their BAU levels of remaining lifetime utility. The 7.7 percent UWIF gain is, as expected, significantly higher than the 4.3 UWI gain. Moreover, UWIF policy does reduce the very high taxes facing many future cohorts. However, it still leaves future generations in otherwise badly hurt regions facing very high net taxes. In India's case, the net tax peaks at 38.2 percent with the UWIF policy rather than 39.9 percent with the UWI policy.

As an alternative, we consider the aforementioned UWIL policy. Under UWIL, all generations in all regions whose tax is not limited experience a 4.0 percent welfare gain. All tax-limited, region-specific generations experience a larger welfare gain. For example, India's peak gain is 35.6 percent for the generation born in 2285.

Two other sensitivity questions concerns the supply of coal and the substitutability between clean and dirty energy. Our baseline model treats coal reserves, like those of gas and oil, as finite. It also models clean and dirty energy as perfect substitutes. As alternatives, we first assume, following Golosov et al. (2014), that coal reserves are infinite and that any amount of coal can be obtained at a fixed cost. Second, we assume, per Hassler et al. (2012), that clean and dirty energy are combined in a CES function to produce our model's ultimate energy input. But we also assume that the degree of substitutability between clean and dirty energy sources rises through time, either smoothly or discretely. Either way, by year 300 we assume the two energy sources are perfect substitutes.

Assuming coal's supply curve is flat makes a major difference to our no-policy (business as usual results), but little difference when optimal carbon policy is in place. Policy simply adjusts to the nature of carbon's supply. However, since the BAU transition is far worse when carbon's supply is unlimited, the gains from fixing the carbon externality are larger. In contrast, carbon policy cannot readily offset a slower transition to full clean for dirty substitutability. As one would expect, dirty energy usage is greater as are global damages when full substitutability of the two forms of energy takes longer. Interestingly, maximum UWI gains from carbon taxation are very similar regardless of the pace of substitutability. In the short run, optimal carbon taxes are quite similar regardless of our assumed pace of substitutability. But over time, the optimal carbon tax is higher the faster the pace of substitution. Intuitively, when you can substitute, it makes sense to make that happen. When you cannot, it does not.

One of our model's key advantages is the ability to assess carbon taxation enacted by only a subset of regions. We find that no region can materially improve climate change if it operates solely on its own. Coalitions of regions can make a difference for themselves. For example, if all regions apart from China adopt a UWI carbon policy, their uniform welfare gain would be about 60 percent lower than the value were China also to participate.⁴ This said, the emissions reduction achievable in this century by any coalition that excludes China is far less than half of the reduction were China to be included. In short, China's participation in carbon policy is a sine qua non for real progress against climate change.

Another finding involves Sinn (2009)'s *Green Paradox* — the proposition that delays in implementing carbon taxation can, due to dirty-energy producers' adoption of a *use it or lose it* strategy, dramatically undermine the value of carbon taxation. Indeed, it could render carbon taxation counterproductive. *Use it or lose it* is of most concern when fossil fuels can be extracted at zero marginal cost. Since our model features costly extraction, delay in policy initiation is less of a concern. Unfortunately, the size of the UWI gain is still reduced by 35 percent — to 2.8 percentage points — if the policy's implementation is delayed for 20 years.

Our model also provides insight into a key issue that is largely independent of climate change and climate policy, namely, the future of economic power (i.e., the regional distribution of GDP). Thanks to catch-up productivity growth, China will become the world's dominant economy by the century's end, accounting for almost one-third of world GDP compared with roughly 16 percent today. This is true despite its projected roughly 400 million population decline through 2100. In contrast, the US global GDP share falls from 25 percent now to 16 percent in 2100. In short, based on our model, China and the US switch economic places in the coming decades.

The climate-relevant question is whether a carbon tax policy will impact growth rates enough to materially change shares of world GDP in, for example, 2100. Our model's unequivocal answer is no. With or without carbon taxation, the distribution of long-term global GDP shares is little affected. Yes, India and other regions hurt most by climate change do lose some ground. But the Chinese and U.S. 2100 shares of output are essentially unchanged whether or not there is major carbon damage, let alone carbon policy that ameliorates that damage. The simple explanation is found in our standard specification of climate damage. Total factor productivity, in each region, declines proportionately based on global temperature. Yes, our model entertains different damage functions and, thus,

⁴ This would entail all regions but China taxing carbon at the collective local SCC value and the IMF or a similar agency redistributing welfare gains among generations in all regions apart from China to achieve a UWI gain.

different global temperature-determined percentage reductions in TFP, depending on the initial prevailing temperature. However, the U.S. and China have similar initial climates and, thus, experience, through time, very similar proportionate GDP declines due to the rise in global temperature. Thus, labor-productivity catch-up growth, which happens on a faster scale than climate damage, is the dominant growth driver with or without climate damage (with or without carbon policy) – even major climate damage.

The remaining article is organized as follows. In Section 2, we proceed with a brief review of the related literature. Section 3 presents our model. Section 4 describes the model's calibration. Section 5 presents our findings. Finally, Section 6 concludes.

2. Literature review

There is a vast and growing body of literature on exhaustible resources and climate change emanating from seminal contributions by Hotelling (1931), Solow (1974b,a), and Nordhaus (1979). Our paper builds on early, small-scale OLG models of resource extraction and global warming (see, e.g., Howarth and Norgaard (1990), Howarth (1991a,b), Burton (1993), Pecchenino and John (1994), John et al. (1995), Marini and Scaramozzino (1995), and Burton (1993)). Howarth (1991a) is of particular relevance since he considered, in general terms, how to analyze economic efficiency in OLG models in the presence of natural resources. Howarth and Norgaard (1992) introduced damages to the production function from environmental degradation and studied the problem of sustainable development.⁵ Rasmussen (2003) and Wendner (2001) examine the impact of the Kyoto Protocol on the future course of the energy sector. Wendner (2001) also considers the extent to which carbon taxes can shore up Austria's state pension system. These latter two studies feature large-scale, perfect-foresight, single-country models. However, they omit climate damage.

Howarth and Norgaard (1990), using a pure exchange OLG model, and Howarth (1991b), using a standard OLG model, emphasize that policymakers can choose among an infinite number of Pareto paths in correcting externalities. Clearly, social judgments will matter in deciding which, if any, of such paths to adopt.⁶ The continuum of available Pareto improvements holds in our setting as it does in general. However, only the UWI policy path treats everyone equally, at least percentage-wise. Moreover, a carbon tax cum net transfer policy delivering equal percentage gains to all current and future generations, no matter their region, seems likely to gain universal support. The same is true of UWIL policy since everyone would have a vested interest in ensuring the carbon tax policy is sustainable.

Apart from Kotlikoff et al. (2021), our paper's closest antecedents are Bovenberg and Heijdra (1998, 2002), Heijdra et al. (2006), and Karp and Rezai (2014). Their studies consider the use of debt policy to achieve Pareto improvements in the context of adverse climate change.⁷ However, these models differ from ours in two important ways. First, they confine environmental damages to the utility function. Second, they do not model clean and dirty energy, with dirty energy exhausting in the future based on the speed of technological change in the clean energy sector.

Nordhaus' seminal climate change paper (Nordhaus, 1979) – the Dynamic Integrated Model of Climate and the Economy (DICE) – spawned a massive literature, including Nordhaus' development of the RICE (the Regional Integrated model of Climate and the Economy) model (Nordhaus and Yang, 1996; Nordhaus, 2010, 2015), which examines how region-specific damages from global warming impacts the global problem. Hassler et al. (2020) present a quantitative integrated assessment model (IAM) designed as a dynamic, multi-region general-equilibrium model coupled with climate and carbon-cycle modules. Their IAM setup is aimed toward policy evaluation, focusing on policies that (i) are not necessarily optimal, and (ii) potentially differ quantitatively and qualitatively across regions. Their model features a single infinitely lived agent in each region and region-specific production of clean and dirty energy. Unlike RICE, they model resource extraction explicitly.

Hillebrand and Hillebrand (2020) also posit a dynamic climate model with multiple regions to evaluate how implementing an optimal climate tax affects production, emissions, and welfare in each region. Their model distinguishes six major world regions and incorporates a wide array of regional heterogeneities, including a detailed description of the energy production process in each region. As in Hassler et al. (2020), there is a single infinitely lived agent in each region. However, in contrast to Hassler et al. (2020), they assume international capital mobility. Interestingly, their model's optimal tax policy is independent of transfers across regions since, with identical homothetic utility across all agents, neither the interest rate nor emissions are affected by the wealth distribution. This is quite different from our results, where transfers across generations can have large effects on the world interest rate.

Krusell and Smith (2022) consider a model with 19,000 regions and studies the distributional effects of climate change and climate policy. As detailed below, we use their calibration strategy to obtain region-specific damages. The main upshot of their work is that since cold regions gain and other regions lose via climate change, a Pareto-improving carbon tax requires transfers to the very cold regions. Below, we use the same functional form for specifying regional damages as proposed by Krusell and Smith (2022), but apply our calibration.

⁵ An alternative approach to incorporating a negative environmental externality is to include environmental quality directly in the utility function. Pecchenino and John (1994) and John et al. (1995) make this assumption in a discrete-time OLG model. Marini and Scaramozzino (1995) do the same but in a continuous-time OLG framework. The problem of generational equity and sustainable development is also discussed by Mourmouras (1991, 1993) and Batina and Krautkraemer (1999) in a model where energy is renewable.

⁶ Gerlagh and Keyzer (2001) and Gerlagh and van der Zwaan (2001) consider the choice among Pareto paths and the potential use of trust-fund policies to provide future generations a share of the income derived from the exploitation of natural resources. Gerlagh and van der Zwaan (2001) also point out that demographics can impact the set of efficient policy paths through their impact on the economy's general equilibrium.

⁷ Karp and Rezai (2014) also consider a life-cycle model but explore the degree to which policy-induced general equilibrium changes in factor and asset prices could effect a Pareto improvement with no direct redistribution across generations.

Cruz and Rossi-Hansberg (2021) develop a dynamic economic assessment model of the world economy with high spatial resolution. Their model features several endogenous climate-adaptation mechanisms absent in our paper. These include costly migration, changes in fertility, alterations in patterns of trade, and impacts on technological change. This aside, our model's structure is very different. In particular, our model includes finite-lived selfish agents, dirty energy and capital mobility, and region-specific technologies for producing output. In addition, we focus on Pareto efficiency rather than social welfare. The difference in objective functions non-withstanding, Cruz and Rossi-Hansberg (2021) estimate local climate damages generally in line with our estimates.

A series of papers on the economic geography of climate change (Peri and Robert-Nicoud, 2021) are also of relevance. They discuss how climate change yields heterogeneous effects across space, and they stress that geographic mobility as a key form of climate adaptation (Conte et al., 2021; Castells-Quintana et al., 2020; Indaco et al., 2020; Bosetti et al., 2020; Grimm, 2019), an issue earmarked for our own future research. Finally, there is literature on optimal carbon pricing together with cross-regional transfer schemes designed to maximize participation (see Klis and McGinty (2022)). We discuss a simple institutional setup that can facilitate, but not guarantee, compliance in our setup.

3. The model

We first describe in Section 3.1 our model's region-specific representative firm and then, in Section 3.2, households. In Section 3.3, we define a competitive equilibrium. Finally, Section 3.4 describes the climate emulator used in our computations, and Section 3.5 the computational method to solve the model. For the detailed calibration of the model presented in this section, we refer to Section 4 and Appendix A.1, whereas Appendix A.3 provides additional details on the solution procedure.

3.1. Firms

Firms in each region, z , in each period, t , produce final output, $Y_{z,t}$, with capital, $K_{z,y,t}$, labor, $L_{z,y,t}$, and energy, $E_{z,t}$, according to

$$Y_{z,t} = A_{z,t} K_{z,y,t}^{\alpha_z} L_{z,y,t}^{\beta_z} E_{z,t}^{1-\alpha_z-\beta_z}, \quad (1)$$

where the subscript y denotes the use of capital and labor in producing final output, and α_z and β_z are region-specific final-output capital and labor shares. $A_{z,t}$ references region-specific total factor productivity (TFP).

Profit maximization implies

$$\alpha_z A_{z,t} K_{z,y,t}^{\alpha_z-1} L_{z,y,t}^{\beta_z} E_{z,t}^{1-\alpha_z-\beta_z} = r_t + \delta, \quad (2)$$

$$\beta_z A_{z,t} K_{z,y,t}^{\alpha_z} L_{z,y,t}^{\beta_z-1} E_{z,t}^{1-\alpha_z-\beta_z} = w_{z,t}, \quad (3)$$

and

$$(1 - \alpha_z - \beta_z) A_{z,t} K_{z,y,t}^{\alpha_z} L_{z,y,t}^{\beta_z} E_{z,t}^{-\alpha_z-\beta_z} = p_{z,t}, \quad (4)$$

where r_t is the world interest rate, reflecting our assumption of perfect capital mobility. The term δ denotes the capital's depreciation rate, assumed identical across regions. The terms $w_{z,t}$ and $p_{z,t}$ reference, respectively, region-specific wages and energy prices at time t .

Clean energy production, $S_{z,t}$, obeys

$$S_{z,t} = B_{z,t} K_{z,s,t}^{\theta} L_{z,s,t}^{\varphi} H_{z,t}^{1-\theta-\varphi}, \quad (5)$$

where $B_{z,t}$, $K_{z,s,t}$, $L_{z,s,t}$, $H_{z,t}$ reference, respectively, the clean energy sector's region- and time-specific productivity level and its demands for capital, labor, and land, where s references clean energy. The parameters θ and φ are clean-energy production parameters.

Profit maximization in producing clean energy requires

$$p_{z,t}^S \theta B_{z,t} K_{z,s,t}^{\theta-1} L_{z,s,t}^{\varphi} H_{z,t}^{1-\theta-\varphi} = r_t + \delta, \quad (6)$$

$$p_{z,t}^S \varphi B_{z,t} K_{z,s,t}^{\theta} L_{z,s,t}^{\varphi-1} H_{z,t}^{1-\theta-\varphi} = w_{z,t}, \quad (7)$$

and

$$p_{z,t}^S (1 - \theta - \varphi) B_{z,t} K_{z,s,t}^{\theta} L_{z,s,t}^{\varphi} H_{z,t}^{-\theta-\varphi} = n_{z,t}, \quad (8)$$

where $n_{z,t}$ is the region- z , time- t rental price of land and $p_{z,t}^S$ is region z 's price of clean energy.

Total regional energy consumption satisfies

$$E_{z,t} = S_{z,t} + E_{z,t}^D, \quad (9)$$

where $E_{z,t}^D$ is a dirty energy composite produced via a CES production function, namely

$$E_{z,t}^D = \left(\kappa_{z,O}^{\frac{1}{u}} O_{z,t}^{\frac{u-1}{u}} + \kappa_{z,G}^{\frac{1}{u}} G_{z,t}^{\frac{u-1}{u}} + \kappa_{z,C}^{\frac{1}{u}} C_{z,t}^{\frac{u-1}{u}} \right)^{\frac{u}{u-1}}, \quad (10)$$

where $O_{z,t}$, $G_{z,t}$, and $C_{z,t}$ reference oil, gas, and coal consumption, respectively, measured in British thermal units (Btu). The terms κ_O , κ_G , and κ_C are CES share coefficients. The parameter u represents the elasticity of substitution between different dirty energy sources.

One can question, per Hassler et al. (2012), at least the short-run realism of perfectly clean and dirty energy substitutability. One way to handle this issue is to assume a gradual increase in the degree of clean and dirty energy substitutability, with the two forms of energy ultimately becoming perfect substitutes. We reformulate our model in this manner in Section 5.3 below, considering three alternative paths to perfect substitutability. Although short- and medium-term use of dirty energy, particularly coal, is greater the slower the transition to full substitutability, the optimal paths of carbon taxation and UWI welfare gains are barely changed.

Oil, gas, and coal trade freely on the world market at prices p_t^O , p_t^G , and p_t^C . Clean energy is non-tradeable. Cost minimization in producing a unit of dirty energy implies the following demands for alternative dirty energies:

$$O_{z,t} = \kappa_{z,O} E_{z,t}^D \left(\frac{p_t^O}{p_{z,t}^D} \right)^{-u}, \quad (11)$$

$$G_{z,t} = \kappa_{z,G} E_{z,t}^D \left(\frac{p_t^G}{p_{z,t}^D} \right)^{-u}, \quad (12)$$

$$C_{z,t} = \kappa_{z,C} E_{z,t}^D \left(\frac{p_t^C}{p_{z,t}^D} \right)^{-u}, \quad (13)$$

where the price of the dirty energy composite is given by

$$p_{z,t}^D = \left(\kappa_{z,O} (p_t^O)^{1-u} + \kappa_{z,G} (p_t^G)^{1-u} + \kappa_{z,C} (p_t^C)^{1-u} \right)^{\frac{1}{1-u}}. \quad (14)$$

Decreasing returns to scale in the clean-energy production sector ensures nonzero production of clean energy in each region regardless of the price of energy. Thus, $S_{z,t} > 0$ holds in equilibrium as well as $p_{z,t} = p_{z,t}^S$. On the other hand, the price of the dirty energy composite, $p_{z,t}^D$, can exceed the price at which energy demand is fully met by clean energy. When this occurs in a given region, there is no demand for the dirty energy composite, and the use of fossil fuels ends. The following equations encompass this outcome. They reflect cost minimization and the constraint that dirty-energy consumption is non-negative.

$$p_{z,t} = p_{z,t}^D - \chi_{z,t}, \quad (15)$$

$$\chi_{z,t} E_{z,t}^D = 0, \quad (16)$$

$$E_{z,t}^D \geq 0, \quad (17)$$

and

$$\chi_{z,t} \geq 0. \quad (18)$$

Note that when dirty energy production is zero, its Lagrange multiplier, $\chi_{z,t}$, is positive, indicating, from Eq. (15), that producing a unit of dirty energy costs more than producing a unit of clean energy.

Dirty energy producers, indexed by their energy-type, $M \in \{O, G, C\}$, have finite energy reserves, R_t^M . The costs of extracting these reserves are increasing in the cumulative amounts extracted. We posit the following functional form for the extraction cost of dirty energy of type M per unit of dirty energy extracted:

$$c_t^M(R_t^M) = \left(\xi_1^M + \xi_2^M (R_0^M - R_t^M) + \left(\frac{1}{R_t^M} \right) \right), \quad (19)$$

where R_0^M denotes reserves at $t = 0$, and ξ_1^M as well as ξ_2^M are parameters given in Section 4. Note that the last term in Eq. (19) ensures that all three extraction costs approach infinity as reserves approach zero.

Dirty energy firms maximize market value, V_t^M , given by

$$V_t^M = \sum_{j=0}^{\infty} \left[(p_{t+j}^M - c_{t+j}^M(R_{t+j}^M) - \phi^M \tau_{t+j}) M_{t+j} + \mathcal{T}_{t+j}^M \right] \left(\prod_{i=0}^j \frac{1}{1+r_{t+i}} \right), \quad (20)$$

subject to

$$R_t^M = R_{t-1}^M - M_t, \quad (21)$$

$$-R_t^M \leq 0, \quad (22)$$

and

$$-M_t \leq 0, \quad (23)$$

where p_t^M is the global price of a unit of dirty energy, M_t , at t , ρ^M is the amount of CO2 emitted per unit of energy of type M (measured in Btu), τ_t is the absolute tax per unit of CO2 emitted at t , and \mathcal{T}_t^M is the lump-sum rebate of time- t carbon taxes to type M dirty energy producers.

The dirty-energy Kuhn–Tucker conditions are given by

$$p_t^M - c_t^M(R_t^M) - \rho^M \tau_t - \ell_t^M + \mu_t^M = 0, \quad (24)$$

and

$$\frac{\partial c_t^M(R_t^M)}{\partial R_t^M} M_t + \ell_t^M - \frac{\ell_{t+1}^M}{1+r_{t+1}} - \psi_t^M = 0, \quad (25)$$

where ℓ_t , ψ_t and μ_t are non-negative Lagrange multipliers for the restrictions in Eqs. (21), (22), and (23), respectively.

The complementary slackness conditions are given by:

$$M_t \mu_t^M = 0, \quad (26)$$

and

$$R_t^M \psi_t^M = 0. \quad (27)$$

The value of land, $Q_{z,t}$, equals the present value of future land rents, that is:

$$Q_{z,t} = \sum_{j=0}^{\infty} n_{z,t+j} H_{z,t+j} \left(\prod_{i=0}^j \frac{1}{1+r_{t+i}} \right). \quad (28)$$

3.2. Households

Agents enter the workforce at age 20 and face an annual idiosyncratic mortality risk through age 100, that is, their maximum age of life. Age-specific mortality risk, which is region- and year-specific, is fully hedged via an actuarially fair annuities market.⁸ Region- and year-specific fertility and mortality probabilities by age are calibrated based on UN demographic projections (see [United Nations \(2019a\)](#) and [United Nations \(2019b\)](#)).

Agents born in region z in year t maximize

$$U_{z,t} = \sum_{j=1}^{80} P_{z,t+j-1,j} \frac{1}{(1+\rho)^j} \frac{C_{z,t+j-1,j}^{1-\sigma} - 1}{1-\sigma}, \quad (29)$$

subject to

$$a_{z,t+1,j+1} = (1+r_t)a_{z,t,j} + w_{z,t} l_{z,t,j} P_{z,t,j} + \mathbb{T}_{z,t,j} - P_{z,t,j} C_{z,t,j}, \quad (30)$$

where $C_{z,t,j}$, $l_{z,t,j}$, $P_{z,t,j}$, and $a_{z,t,j}$ reference, respectively, consumption, labor supply, population size, and assets of age- j agents born in the region z at time t . The term $\mathbb{T}_{z,t,j}$ references net transfers received at age j by the generation born at t in the region z . Finally, ρ is the time preference rate, and σ is the coefficient of relative risk aversion.

3.3. Equilibrium and debt-policy

Total household assets comprise physical capital, the value of dirty energy firms, the value of land, and carbon-policy debt, that is,

$$\sum_{z=1}^{18} \sum_{j=1}^{80} a_{z,t,j} = K_t + V_t^O + V_t^G + V_t^C + \sum_{z=1}^{18} Q_{z,t} + D_t, \quad (31)$$

where D_t is debt issued to finance carbon policy and where

$$K_t = \sum_{z=1}^{18} K_{z,y,t} + \sum_{z=1}^{18} K_{z,s,t}. \quad (32)$$

Debt evolves according to

$$D_{t+1} = (1+r_t)D_t + \sum_{z=1}^{18} \sum_{j=1}^{80} \mathbb{T}_{z,t,j}. \quad (33)$$

The world supplies of oil, gas, and coal equal the sum of regional demands

$$O_t = \sum_{z=1}^{18} O_{z,t}, \quad G_t = \sum_{z=1}^{18} G_{z,t}, \quad C_t = \sum_{z=1}^{18} C_{z,t}. \quad (34)$$

⁸ This precludes needing to model bequests and inheritances.

Finally, regional supplies of labor equal the sum of their sectoral demands.

$$L_{z,t} \equiv \sum_{j=1}^{80} P_{z,t,j} l_{z,t,j} = L_{z,y,t} + L_{z,s,t}. \quad (35)$$

We denote by IMF a hypothetical international institution that coordinates global carbon policy.⁹ The IMF needs to assess a net tax of $\mathbb{T}_{z,j,t}$ on generation j in region z in each year t . Budget balance implies that

$$\sum_{t=0}^{\infty} \left(\prod_{\tau=0}^t \frac{1}{1+r_{\tau}} \right) \sum_{z=1}^{18} \sum_{j=1}^{80} \mathbb{T}_{z,t,j} = 0, \quad (36)$$

or in other words, where debt policy satisfies

$$\lim_{t \rightarrow \infty} D_{t+1} \left(\prod_{\tau=0}^t \frac{1}{1+r_{\tau}} \right) = 0.$$

3.4. Modeling the climate

To describe the evolution of the climate in our multi-region OLG model, we adopt the functional form of DICE (Nordhaus, 2017), which relates output to emissions, emissions to carbon concentration, and carbon concentration to global temperature, but use a parameterization proposed by Folini et al. (2024) and which is based on the latest findings from climate science.¹⁰

DICE mimics the carbon cycle via three carbon reservoirs: the atmosphere (A), the upper ocean (U), and the lower ocean (L). The process by which output increases atmospheric carbon concentration is given by

$$\begin{pmatrix} J_t^A \\ J_t^U \\ J_t^L \end{pmatrix} = \Phi^J \begin{pmatrix} J_{t-1}^A \\ J_{t-1}^U \\ J_{t-1}^L \end{pmatrix} + \begin{pmatrix} \rho^O O_t + \rho^G G_t + \rho^C C_t + E_t^{Land} \\ 0 \\ 0 \end{pmatrix}, \quad (37)$$

where J_t^A , J_t^U , J_t^L are the CO_2 concentrations in the atmosphere, the upper ocean, and the lower ocean. Φ^J is a 3 by 3 matrix of parameters governing the mass transfer across the three reservoirs with units “mass fraction per time step”. E_t^{Land} is land-based carbon emission, which obeys the following relationship.

$$E_t^{Land} = E_0^{Land} e^{-\delta^{Land} t}, \quad (38)$$

where δ^{Land} is the rate at which land-based emissions decline. CO_2 in the atmosphere impacts radiative forcing, F_t , according to

$$F_t = \eta_1 \frac{\log \frac{J_t^A}{J^0}}{\log(2)} + F_t^{EX}, \quad (39)$$

where J^0 is the pre-industrial concentration of atmospheric carbon. F_t^{EX} references time- t radiative forcing, which is assumed to evolve as

$$F_t^{EX} = F_0^{EX} + \frac{1}{T'} (F_1^{EX} - F_0^{EX}) \min(t, T'), \quad (40)$$

where F_0^{EX} and F_1^{EX} are the exogenous values of radiative forcing in the initial period, 2017 and 2100, respectively. T' references years between 2017 and 2100.

In DICE, the temperature evolves according to a two-layer energy balance model, that is,

$$\begin{pmatrix} T_t^A \\ T_t^L \end{pmatrix} = \Phi^T \begin{pmatrix} T_{t-1}^A \\ T_{t-1}^L \end{pmatrix} + \begin{pmatrix} \eta_2 F_t \\ 0 \end{pmatrix}, \quad (41)$$

which formally corresponds to the evolution described in Geoffroy et al. (2013). In Eq. (41), T_t^A and T_t^L denote the global mean temperature change, relative to pre-industrial levels, of the upper layer (atmosphere and upper ocean) as well as the lower layer (deep ocean), respectively, at the time step t . From a physics perspective, the free parameters in Eq. (41), including the matrix Φ^T , may be interpreted as a heat exchange coefficient between the upper and lower layers, the effective heat capacities of the upper and lower layer, and the ratio of forcing arising from a doubling of CO_2 to the associated temperature change.

Our IAM requires knowledge of regional climate damages and, thus, regional temperatures. We infer regional from global temperature using a popular technique from climate sciences called “pattern scaling” (see, e.g., Tebaldi and Arblaster (2014), Lynch et al. (2017), Kravitz et al. (2017), and references therein). Pattern scaling, first introduced by Santer et al. (1990), is a statistical method that, based on large-scale Earth system models, relates, for instance, the global average temperature, T_t^A , in a computationally efficient fashion to local temperatures at resolutions as fine as about 1° longitude \times 1° latitude.

⁹ This is the Lump Sum Redistribution Authority (LSRA) of Auerbach and Kotlikoff (1987).

¹⁰ The parameters governing carbon concentration are provided in Section 4.

Our computations use the publicly available pattern-scaling repository by Lynch et al. (2017).¹¹ Specifically, we use the CCSM4 model that follows the RCP8.5 for all our computations. Our results are robust to the choice of RCP scenarios in connecting global average temperature to grid-specific and, thus, region-specific temperature (Link et al., 2019).

In computing the regional average surface temperatures, $T_{z,t}$, we apply pattern scaling as follows. First, we compute T^A (cf. Eq. (41)). Second, we derive local temperatures on a 1° by 1° grid, each of which belongs to a certain region of our model. Third, we use cell-specific GDP values to weigh cell-specific temperature values to produce our regional GDP-weighted average temperatures.¹²

The “handshake” of the climate emulator and the economics block of the model is done at the level of temperature-dependent damages to TFP. We model regional TFP, $A_{z,t}$, as the product of a region-specific exogenous trend, $\bar{A}_{z,t}$, and a regional function, $Z_{z,t}$, which incorporates productivity differences due to differences in temperature. $\bar{A}_{z,t}$ grows at a time-varying, region-specific growth rate $g_{z,t}$, that is,

$$\frac{\bar{A}_{z,t}}{\bar{A}_{z,t-1}} = 1 + g_{z,t}. \quad (42)$$

Following Krusell and Smith (2022), we assume that the component $Z_{z,t}$ obeys

$$Z_{z,t} = \begin{cases} 0.02 + 0.98e^{(-v^+(T_{z,t}-T^*)^2)} & \text{if } T_{z,t} > T^*, \\ 0.02 + 0.98e^{(-v^-(T_{z,t}-T^*)^2)} & \text{if } T_{z,t} \leq T^*. \end{cases} \quad (43)$$

Regional climate damages are given by

$$D_{z,t} = 1 - Z_{z,t} / Z_{z,1900}. \quad (44)$$

Eq. (43) models regional climate-specific TFP as peaking at T^* (cf. Krusell and Smith (2022)). Thus, cold regions with temperatures below T^* will benefit from global warming as their temperature approaches T^* . Similarly, hot regions will be harmed as their temperature moves farther away from T^* . Larger values of v^+ and v^- raise the cost of a given deviation from the optimal temperature. In our calibration below (cf. Section 4 and Fig. 13 in the Appendix), we choose v^+ to relate regional damage functions to the global damage functions used in the literature.¹³

3.4.1. The social cost of carbon

We define the SCC at t to be the present discounted value of all future damages resulting from an additional unit of CO2 emitted at t . In much of the existing literature (see, e.g., Nordhaus (1979) or Golosov et al. (2014)), this cost is equal to a marginal rate of substitution of a social planner's value function. As explained in the introduction, our model features no social planner. Consequently, we need to determine the SCC by solving for the evolution of temperature and damages for two different emissions paths. We define the SCC at some time τ as the sum of all damages at times $\tau, \tau+1, \dots, \infty$ that arise when one extra unit of CO2 is added exogenously to emissions given by Eq. (37), discounted at the path of the equilibrium world interest rate, minus the discounted sum of all damages that arise without this extra unit. Pareto efficiency requires setting the carbon tax each period to that period's SCC.

3.5. Computational method

Our solution method uses a variant of the Gauss–Seidel iteration technique developed in Auerbach and Kotlikoff (1987). Specifically, it begins with guesses of the level of the UWI welfare gain and the time paths of the aggregate capital stock, oil, coal, gas reserves, global emissions, region-specific total factor productivities, and the carbon tax. It then uses a recursion to solve the model backward from its steady state, which the economy is assumed to reach in 3017. A millennium is clearly a very long time for the economy to stabilize. But it provides the climate's atmospheric carbon concentration sufficient time to stabilize. The recursion determines, on a year-by-year basis, all region-specific and global prices, including the world interest rate, and all region-specific quantities, including all inputs, outputs, and consumption amounts of all cohorts. It also calculates the region- and cohort-specific lump-sum net transfers needed to achieve the guessed UWI gain. These recursively calculated values are used to update the time paths of our guessed global aggregates, regional temperatures, regional damages, regional productivities, and the carbon tax. In addition, we raise (lower) the targeted UWI gain if the present value of net transfers across all regions and generations is negative (positive). Our algorithm is highly precise. Its annual variables converge, relative to their prior guessed values, to less than one-hundredth of one percent. Supplementary details on the algorithm are provided in Appendix A.3.

¹¹ The respective data sets and codes can be found at URL: https://github.com/JGCR1/CMIP5_patterns. Each function relating the local average to the global average temperature is determined by using calculations from dozens of large-scale climate models developed by climate scientists across the world. Their calculations are organized by CMIP5 (Taylor et al., 2012) – the Coupled Model Intercomparison Project Phase 5, which collects climate-model calculations for specific greenhouse gas scenarios called representative concentration pathways (RCP). The four primary RCP scenarios are denoted as RCP2.6, RCP4.5, RCP6, and RCP8.5. Each RCP scenario generates particular paths of greenhouse gases, aerosols, and other climatically relevant forcing agents over the 21st century. The RCP8.5 scenario, for instance, reflects a “BAU” narrative, in which total anthropogenic forcing reaches approximately 8.5 W/m^2 in the year 2100. Conversely, the RCP2.6 scenario involves aggressive decarbonization, causing radiative forcing to peak at approximately 3 W/m^2 around 2050 and to decline to approximately 2.6 W/m^2 at the end of the 21st century. For the exact specifications of the RCP scenarios and related data, see Meinshausen et al. (2011), and <http://www.pik-potsdam.de/~mmalte/rcps/>.

¹² Note that we leverage Nordhaus' G-Econ database to construct the GDP-weighted regional temperature patterns (see <https://gecon.yale.edu>, GEcon 4.0 for 2005). This weighting ensures that the location of human activity dominates the average temperature within a region. In Canada, for example, the GDP-weighted average temperature is concentrated in regions close to the US, whereas the naive average would be driven by cells closer to the North Pole.

¹³ The notion that some regions might gain from climate change is controversial, given the potential for tipping points causing catastrophic global climate events. However, our certainty-equivalent approach requires incorporating climate-change gains as well as losses.

Table 1

The left and right columns below present the acronyms of our model's 18 global regions.

Acronym	Region
ANZ	Australia and New Zealand
BRA	Brazil
CND	Canada
CHI	China
EEU	Eastern Europe
GBR	The U.K.
IND	India
JSHK	Japan, South Korea, and Hong Kong
MENA	Middle East and North Africa
MEX	Mexico
RUS	Russian Federation
SAF	South Africa
SAP	The South Asian Pacific
SLA	Latin America excluding Mexico and Brazil
SOV	Former Soviet Central Asia
SSA	Sub-Saharan Africa
US	USA
WEU	Western Europe

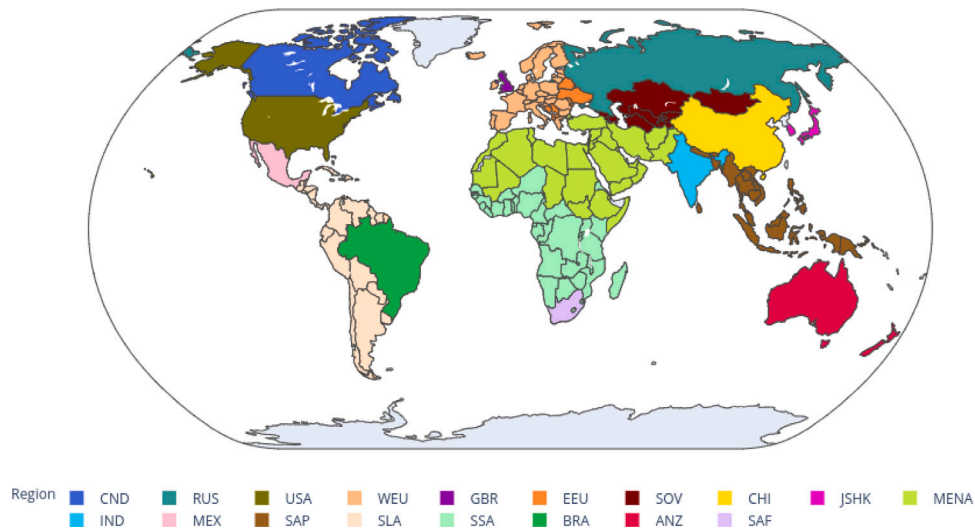

Fig. 1. This figure depicts the 18 regions of our model and the corresponding color coding. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

4. Calibration

This section summarizes the key components of our calibration strategy, whereas [Appendix A.1](#) provides additional details. Our 18-region OLG model builds on the so-called Global Gaidar Model (GGM; cf. [Benzell et al. \(2017\)](#)), but is substantially extended by coupling it to a climate emulator (cf. [Section 3.4](#)) and by adding an extra region.¹⁴ [Table 1](#) lists the model's 18 regions and their acronyms, and [Fig. 1](#) displays them on a map of the globe. The World Bank's Development Indicators (WDI) is a primary data source, providing, in particular, 2017 GDP values. These are used to calibrate the 2017 levels of regional TFP. Energy consumption/usage data come from the US Energy Information Administration (EIA). These data, measured in Btus, comprise four categories: (i) coal, (ii) natural gas, (iii) petroleum and other liquids, (iv) nuclear, renewables, and others. We aggregate energy sources into four composites: coal, gas, oil, and clean energy. [Table 2](#) presents region-specific GDP and energy-consumption data.

The EIA data let us calibrate the region-specific CES production functions specified in [Eq. \(46\)](#). As in [Hillebrand and Hillebrand \(2020\)](#), we assume an elasticity of substitution between oil, coal, and gas of $u = 2$. This value lies between [Acemoglu et al. \(2012\)](#)'s (higher) and [Golosov et al. \(2014\)](#)'s (lower) assumed values. We measure the share parameters, κ_O , κ_G , and κ_C , using data on 2017 world energy prices. Taking the 2017 \$50.8 price per barrel of West Texas Intermediate crude and assuming that one barrel of oil

¹⁴ In particular, the GGM's single region consisting of Canada, Australia and New Zealand is split into Canada by itself and ANZ — Australia plus New Zealand.

Table 2

This table presents region-specific GDP and energy-consumption data. Each row presents the 2017 GDP (in trillions of 2017 USD) and energy consumption (in quad Btus) of coal, natural gas, petroleum and other liquids, nuclear, renewables, and others per individual region.

	GDP (<i>Y</i>)	Coal (<i>C</i>)	Natural Gas (<i>G</i>)	Petroleum and Other Liquids (<i>O</i>)	Nuclear, Renewables, and Other (<i>S</i>)

contains $5.7 \cdot 10^6$ Btus, our 2017 price of oil equals $8.9 \cdot 10^{-6}$ per Btu. Analogous calculations produce a 2017 price of gas of $5.7 \cdot 10^{-6}$ per Btu and a price of coal of $4.5 \cdot 10^{-6}$ per Btu. Normalizing the sum of κ_O , κ_G , and κ_C to 1, and using Eqs. (11)–(13) provides our region-specific, dirty-energy share parameters. These coefficients are then used to construct the price of the dirty-energy composite per equation (14). This also pins down the 2017 price of clean energy as well as the 2017 dirty-energy consumption by region.

The ratio of each region's total energy consumption as a share of its GDP provides our measure of $1 - \alpha_z - \beta_z$. To determine values for α_z and β_z , we assume that one-third of this remaining output share is paid to capital with the rest paid to labor.

Table 3 reports region-specific contributions of energy to output as well as contributions of particular energy sources. The table shows remarkable differences across regions in energy reliance — from 2.25 percent of GDP in Great Britain to 14.67 percent in SOV (former Soviet states in Asia). Table 2 also reports our calculated 2017 region-specific GDP and dirty-energy usage levels. The major consumers of fossil fuels are China, at 122.14 quad Btus, the US at 80.01 quad Btus, and Western Europe at 49.26. Even though China's 2017 GDP is less than two-thirds that of the US and only three-fourths that of the WEU, its carbon emissions are twice that of the US and three times that of the WEU. This reflects its overwhelming dependence on coal, which arises from its very high value of κ_C . Indeed, the Chinese value of κ_C is almost seven times that of the US. However, the US is hardly a model green citizen. US GDP is one-fifth larger than that of WEU. However, its emissions are three-fifths larger. For further comparisons, Table 8 in the Appendix shows region-specific GDP, energy consumption, and CO2 emissions relative to the USA.

We adopt $\theta = 0.13$ and $\varphi = 0.27$, the clean-energy production parameters specified in Eq. (5), from Kotlikoff et al. (2021). In particular, we assume that 60 percent of clean energy output is paid to land, with the rest distributed between labor and capital in

Table 4

the same proportion as in the final goods sector. In calibrating TFP levels in the final goods and clean energy production sectors, we assume a 10 percent annual capital depreciation rate and a 4 percent base-year global real interest rate. This implies a 14 percent rental rate on capital. With this rental price, data on regional labor endowments, calculated values of output, and the levels of clean and dirty energy consumption, we compute regional capital demands and TFP values in both sectors using Eqs. (1)–(7). This delivers the year 2017 value of world capital equal to \$178 trillion.¹⁵

To calibrate region-specific productivity growth in final goods production, we rely on univariate, country-specific regressions graciously provided by Müller et al. (2019). We aggregated the country estimates to generate regional productivity growth rates. Table 4 presents these productivity rates relative to the US productivity growth rate. The depicted productivity growth rate differentials are applied through 2100. After 2100, we assume that productivity growth in all regions equals the assumed fixed 1.56 percent US growth rate. As for productivity growth in clean energy, we set it to generate a 0.5 percent per year decline in the steady-state energy price.

We use United Nations population projections (United Nations, 2019b) to calibrate population dynamics. These data account for fertility, mortality, and migration. Fig. 12 in Appendix A.1 provides a graphical summary of these data. As indicated, there are pronounced demographic waves in some regions, particularly in Russia. The initial distribution of assets between generations and regions is taken from Benzell et al. (2017). The time preference rate, ρ , is calibrated at 1.5 percent per year. The coefficient of relative risk aversion, σ , is set to 1.45.

Based on McGlade and Ekins (2015), we calibrate the globally available oil reserves to 600 GtC, globally available gas reserves to 400 GtC, and globally available coal reserves to 2700 GtC. We assume CO2 emissions of 97.5 kg per million Btu of coal, 72.6 kg per million Btu of oil, and 53.1 kg per million Btu of natural gas, which helps us calibrate ρ^M .¹⁶ In calibrating our extraction cost parameters, we assume that the extraction costs double when the available reserves decline by half. This assumption links ξ_2^M with ξ_1^M in Eq. (19). Then, we solve for the values of ξ_1^M that reproduce the 2017 energy prices under BAU.

The parameters for the climate block of the DICE model (cf. Section 3.4) are adopted from Folini et al. (2024).¹⁷ The 2017 land emissions, E_t^{Land} , are calibrated at 0.709 GtC, and that annual rate of reduction in land emissions, δ^{Land} , at 0.023. Radiative forcing in 2017 and 2100, F_0^{EX} and F_1^{EX} , are set to 0.5 and 1, respectively. The radiative-forcing sensitivity parameter, η_1 , is set at 3.45. The parameter determining how global mean surface temperature responds to radiative forcing, η_2 , is set at 0.137. Initial values for climate variables are calibrated as $J_0^A = 898$ GtC, $J_0^U = 816$ GtC, $J_0^L = 1809$ GtC, $T_t^A = 1.49$ Celsius change since 1900, and $T_t^L = 0.378$ Celsius change since 1900. The equilibrium concentration in the atmosphere, J^0 , is set at 607 GtC.

Following Folini et al. (2024), the parameter matrices Φ^J and Φ^T are specified as:

$$\Phi^J = \begin{pmatrix} 0.928 & 0.0728 & 0 \\ 0.072 & 0.923 & 0.0014 \\ 0 & 0.0042 & 0.9986 \end{pmatrix}, \Phi^T = \begin{pmatrix} 0.7546 & 0.1 \\ 0.0069 & 0.9931 \end{pmatrix}. \quad (45)$$

As for regional damages, we follow Krusell and Smith (2022) in setting $T^* = 11.6$ in Eq. (43). In our most optimistic calibration, $\nu^+ = \nu^- = 0.001$. Recall, these are damage-sensitivity parameters arising from the regional temperature in Eq. (43).

However, this scenario seems overly optimistic along two dimensions. First, our climate calibration uses the multi-model mean from CMIP5 as a target. However, CMIP5 produces a large range of predictions, and the more pessimistic ones entail much higher temperatures (see Folini et al. (2024)). Moreover, the Krusell–Smith calibration for global damages takes DICE-16 as a benchmark. As Nordhaus (2008) points out, “the economic impact of climate change ... is the thorniest issue in climate-change economics”. This is a major and very important theme of Pindyck (2013). Howard and Sterner (2017) conduct a meta-analysis of different global damage functions and argue that the damages might be far larger than assumed in DICE. In our model, damages depend only on the product of the parameter ν and $T_z - T^*$, the regional temperatures in excess of T^* . Hence, we vary the parameter κ to jointly capture different damage functions and degrees of climate sensitivity.

¹⁵ This amount is based on world GDP as estimated by the World Bank, region-specific capital shares governing the production of the final output, the assumed initial global rental price of capital, and region-specific production of clean energy.

¹⁶ See for more details.

¹⁷ Dietz et al. (2021), among others, criticize the climate emulators commonly used in economics, including Nordhaus' widely used DICE model (Nordhaus, 2017). A key functionality that any climate emulator has to provide is to translate anthropogenic emissions, as computed by the economic model, into a global mean temperature change. Emulators typically consist of two parts: The first is a “carbon cycle” that describes how anthropogenic emissions in the wake of human economic activity translate into changes in the CO2 concentration in the atmosphere. The second is a temperature model that determines how the CO2 concentration in the atmosphere translates into an average temperature. The latter, in turn, feeds back again into the economic model. The climate emulator of DICE (cf. Section 3.4) in its original formulation, however, does not accord with the latest physical data. Fortunately, the CMIP5 benchmark data. Folini et al. (2024) provide a suite of test cases that permit a full re-calibration of DICE parameters. Compared to the original DICE model, this leads to less long-term warming because of changes in the carbon cycle.

Fig. 2. Alternative calibrations of “Krusell–Smith”-type productivity functions as a function of temperature, measured in °C. The 2x, 4x, and 6x cases/scenarios reference our low-, medium-, and high-damage scenarios.

We consider cases with $v^+ = 2v^*$, $v^+ = 4v^*$, $v^+ = 6v^*$, where $v^* = 0.001$ corresponds to the value in the most optimistic calibration. We label these as our 2x, 4x, and 6x cases/scenarios and reference them as our low-, medium-, and high-damage scenarios. In all cases, v^- remains fixed at v^* . Fig. 2 depicts the “Krusell–Smith” productivity function (see Eq. (43)). Note that only the right side of the productivity function shifts. In short, we consider higher damages in regions that incur losses from global warming. At the same time, we assume only moderate gains for regions that incur gains from global warming.

5. Results

This section first presents BAU results for our different damage-function specifications. Next, we consider alternative carbon policies, assuming all regions levy annual carbon taxes equal to each year’s global SCC. Our “No Transfers” policy taxes carbon but provides no compensation to those suffering welfare losses. To recapitulate, our UWI policy, as indicated, uniformly allocates efficiency gains to all current and future cohorts in all regions. Our UWIF policy reprises our UWI policy but restricts the uniform welfare gains to only future generations; all current generations receive their BAU utility levels. Our UWIL policy runs UWI under the restriction that the lifetime net tax payment of any generation in any region is limited to 10 percent of that region-specific generation’s lifetime consumption. We also consider carbon policies that are not Pareto-efficient, but that might, nonetheless, arise in the political process.

5.1. Simulating BAU

Table 5 reports the maximal BAU increases in global mean temperature (relative to pre-industrial levels) as well as peak BAU losses and gains by region for our four damage-function specifications detailed in Eq. (44). According to our model, absent carbon policy, the planet’s average temperature will rise by 3.7 to 4.4 degrees Celsius over the next 200 years. Paradoxically, global mean BAU temperature increases are significantly higher in the (1x and 2x) low damage cases because lower damages mean higher GDP and, thus, higher emissions. Despite the higher rise in global temperature, global and regional damages are lower in these cases thanks to their more benign damage functions. Planetary warming under BAU benefits Russia and Canada, whose temperatures rise between 2.8 and 3.8 degrees and 2.7 and 3.6 degrees compared to pre-industrial levels (cf. Fig. 8), respectively. This reflects their initial (2017) very low average temperatures — temperatures far too low to achieve peak productivity.

As indicated, damages under BAU can be extraordinarily large for the world as a whole, but particularly for specific regions. For example, in the 6x damage scenario, global damages peak at almost 17 percent of world output. However, India’s damages reach over 40 percent of GDP by 2200, with this percentage output loss persisting for more than a century. For the US, China, and Japan/South Korea/Hong Kong, the year 2200 damages exceed 16 percent of output with no improvement and, in some cases, a worsening over the following 100 years. GBR experiences small damages, peaking at just 2.1 percent of GDP. Russia and Canada’s climate gains peak above 3.9 percent and 2.6 percent of GDP, respectively. ANZ, SSA, SLA, SAF, MEX, BRA, MENA, and SAP also experience significant damages.

Table 5

Peak BAU losses and gains (negative sign) as a percentage of GDP per region for the 1x, 2x, 4x, and 6x damage scenarios. In addition, the corresponding maximal temperature increases are reported at the end of the table.

	1x	2x	4x	6x
US	4.0	7.4	12.8	17.1
WEU	1.6	2.9	4.9	6.5
JSHK	3.9	7.1	12.4	16.7
CHI	4.0	7.4	12.7	17.0
IND	11.8	21.1	34.6	43.9
RUS	−4.1	−4.1	−4.0	−3.9
CND	−2.7	−2.7	−2.6	−2.6

SSA	9.7	17.5	29.3	37.9
SOV	2.0	3.6	5.9	7.6
GBR	0.5	1.0	1.6	2.1
ANZ	4.6	8.6	14.9	19.9
GLOBAL	4.4	7.9	13.0	16.7
Max. global temperature rise	4.4	4.2	3.9	3.7

The magnitude of global damages is highly sensitive to the shape of the upper tail of the damage function. In the 6x case, peak global as well as regional damages are almost four times larger compared to the 1x damage specification (cf. Table 5). Despite the fact that emissions and temperature increases are significantly lower than in the 1x case (again, because of the paradox that higher damages limit output and, thus, emissions), extreme damages in some regions are far larger.

The close to 17 percent global peak GDP loss in the 6x case lies well within recent projections of climate damages. Hänsel et al. (2020), for instance, strongly criticizes the DICE damage function, advocating alternative specifications that produce larger damages for a given rise in temperature. Cruz and Rossi-Hansberg (2021) provide region-specific damage estimates that are roughly in line with our 6x case.

The damage function is just one of many factors that impact the cost of climate change. As indicated, we calibrate our climate emulator according to the multi-model mean of CMIP5 simulations. Calibrating to more pessimistic scenarios would entail both higher temperatures and higher damages, holding the damage function fixed. In addition, the data to which we calibrate may be understating true fossil-fuel reserves, overstating fossil-fuel extraction costs, and suggest faster clean-energy productivity growth that will arise.

Fig. 3 compares global CO₂ emissions for our 6x BAU scenario over the next 200 years with the emissions projections used in the four RCP scenarios adopted by the Intergovernmental Panel on Climate Change (IPCC)¹⁸ and the emissions in DICE.¹⁹ As the figure shows, our BAU emissions are significantly lower than in DICE or RCP8.5. As Hausfather and Peters (2020) point out, RCP8.5 was intended to explore an unlikely high-risk future, that entails unrealistically high coal usage. In this light, the RCP6.0 scenario seems more relevant for forecasting emissions absent policy. Our baseline BAU emissions path, which falls between the RCP6.0 and RCP4.5 scenarios, represents a relatively optimistic path.

Under BAU, oil, gas, and coal production will definitively end worldwide in 200 years.²⁰ However, dirty energy usage terminates far sooner in some regions. Brazil is the first region to end the use of all fossil fuels in 2045. The US end date of dirty energy usage is 2105. For China, it is 2092.

The BAU transition entails many macroeconomic changes that are only partially impacted by climate change. For example, as will be discussed below (cf. Section 5.2.4), there is a major change in the distribution of world global economic power. By 2100, China and India account for almost 40 percent of world GDP (cf. Table 7). This is true with or without climate policy and reflects our assumed Chinese and Indian catch-up economic growth. Another example is the impact on the global interest rate (cf. Table 6's row called "Long-run interest rate"). The combined faster growth of higher-saving regions, specifically China and India, and the remarkable aging experienced by all regions leads to significant global capital deepening. Absent carbon policy, the global interest rate falls to 2.9 percent by the end of the century from its initial 4.0 percent value. As discussed below, carbon policy can largely reverse this process. Thus, it represents a determinant of capital deepening and interest rates that operates separately from catch-up productivity growth and demographic change.

¹⁸ For more details on the IPCC, see ipcc.ch.

¹⁹ For tractability, the figure omits results based on our more benign damage function. Their emissions are, as indicated, slightly higher.

²⁰ See Figs. 14, 15, and 16 in Appendix A.2, in which projected oil, gas, and coal use, both under BAU and the UWI optimal policy for the 6x damage specification, is shown.

Fig. 3. Global CO₂ emissions (in GtCO₂) in our BAU scenario, DICE 2016, and the different RCP scenarios at a given point in time. The year 0 on the x-axis represents 2017.

5.2. Carbon policies

Table 6 summarizes our key findings. It indicates that optimal initial carbon taxes are extremely sensitive to the damage function. Absent transfers, they range from \$22.8 per ton CO₂ with the 1x damage specification up to \$111.7 per ton with 6x calibration (cf. the row called “Initial optimal tax, \$ per ton of CO₂” in Table 6). The corresponding optimal UWI taxes range from \$22.4 to \$87.5 under UWI. For a given damage specification, the SCC is higher without net transfers for a simple reason. The net transfers associated with, say, the UWI policy entail significant crowding out of capital thanks to the compensatory transfers made to early generations from their future progeny. In the case of the 6x damage specification, this raises the global interest rate under UWI by some 100 basis points relative to taxing carbon but not compensating losers (cf. the row called “Long-run interest rate, percent per year” in Table 6). Since the SCC is a discounted sum of marginal future global damages, the higher global interest rate under UWI policy than with no transfers implies, other things equal, a lower SCC and, thus, lower carbon taxes.²¹ As indicated in Table 6’s row called “Welfare gains”, the UWI carbon policy can achieve a major win-win for all humanity. In the 6x UWI case, all generations, present and future, across all regions gain 4.3 percent. Even in the 4x case, arguably an optimistic damage scenario, the UWI gain is almost 3.0 percent. Without transfers, some generations incur large welfare losses — up to 18.0 percent in the 6x case, while others experience huge gains — up to 47.6 percent.

Maximal global temperature and maximal regional damages are substantially reduced by carbon taxation (cf. the rows called “Max. global damages, percent of global GDP” and “Max. regional damages, percent of regional GDP” in Table 6). However, peak damages are slightly larger with a re-distributive policy than without. Finally, the table shows that the UWI case entails extremely large transfers from future generations in regions hardest hit by climate change (cf. the row called “Minimal regional transfers, percent of the present value of consumption” in Table 6). In the 6x case, Indians born in 200 years would be required under UWI policy to surrender more than 40 percent of their consumption to help service outstanding carbon-policy debt (see Fig. 4). Even in the 2x and 4x cases, transfers under the UWI policy are exceptionally large.²²

5.2.1. Alternative SCC-determined carbon-tax paths

Fig. 5 shows the SCC-determined carbon taxes for the cases of no transfers, UWI, UWIF, and UWIL. The initial carbon tax and its growth rate are the highest when there are no transfers (cf. the row called “Average growth rate of optimal tax over the next 50 years, percent per year” in Table 6). In fact, the carbon tax and, thus, the SCC in year 40 (counting from the year 2017) is almost one-third

²¹ Tables 9 and 10 in Appendix A.2 provide supplementary results on the region-specific SCC for the 6x specification of the damage function.

²² Assuming that ownership of reserves is non-tradeable would significantly complicate our model. In addition, it might render it impossible to calibrate. Yes, oil, gas, and coal reserves are highly unevenly distributed across our 18 regions. However, empirically assessing ownership rights would largely constitute a guessing game. Take the Swiss company Glencore. It manages coal mining in deposits, many of which are located far outside the European Union. Indeed, the company operates mines in 35 different countries. As for ownership of Glencore, its shares are publicly traded.

Table 6

	UWIL	−6.7	−10.0	−10.0	−10.0

higher than, for example, under UWI policy. Hence, optimal carbon taxation cannot be determined without deciding whether and how to distribute the efficiency gains from taxing carbon.

In all four cases, SCC-based carbon taxes grow at time-varying rates, with the tax accelerating after 60 years. Optimal taxes 100 years from now are very high — above \$700 in the no-transfer case. However, the welfare gains from setting a time-varying rather than a fixed growth rate are small, that is, a simple, time-invariant growth in the carbon tax suffices to produce the vast majority of any policy's welfare impacts.

As shown in Table 6 in the cells “Average growth rate of optimal tax over the next 50 years”, the average annual carbon tax real growth rate of the 6x damage specification ranges from 1.4 to 1.5 percent. This is in line with Kotlikoff et al. (2021), which featured a 1.5 percent optimal UWI carbon tax growth rate, albeit in a global, that is, a single-region OLG model. For the 6x case with UWI policy, an initially \$97 carbon tax growing at 1.5 percent per year real – our prior paper's UWI optimal policy – also yields a UWI gain of 4.3 percent up to 2 significant digits. The reason for this is that starting with a high initial tax on carbon leads to an immediate steep reduction of emissions in almost all regions, and a slight variation in the carbon tax rate, which matters only in the long run, has little effect on the time path of emissions (see Fig. 6).

Fig. 7 shows the welfare gains and losses for the different tax-transfer schemes for the 6x damage specification. Note first that absent transfers, many early generations in CHI, IND, RUS, CND, EEU, SAF, MENA, SOV, and GBR are harmed by SCC-based carbon taxation. Moreover, cross-region transfers across contemporaneous generations cannot Pareto improve since there are no welfare gains for generations born around $t = 0$.

UWI makes everyone better off but comes at a very high net tax cost to India and other low-income regions that are most vulnerable to climate change. Consider, then, UWIL policy, which, to repeat, caps net taxes on future generations, regardless of region, at 10 percent. Under this SCC-based carbon taxation, welfare gains are uniform for all region-specific generations not subject to the limit, and higher for those subject to the limit. Maximal welfare gains for future generations are 35.6 percent in IND, 27.2 percent in SAP, 25.2 percent in BRA, 15.5 percent in MEX, 25.9 percent in MENA, 19.5 percent in SLA, and 25.9 percent in SSA (cf. the red dotted lines in Fig. 7).

Interestingly, initial older generations fare better under this policy (cf. Fig. 7). The explanation lies in the policy's implicit monopolization of the dirty-energy section, which raises the prices of dirty energy reserves and, for that matter, the value of land

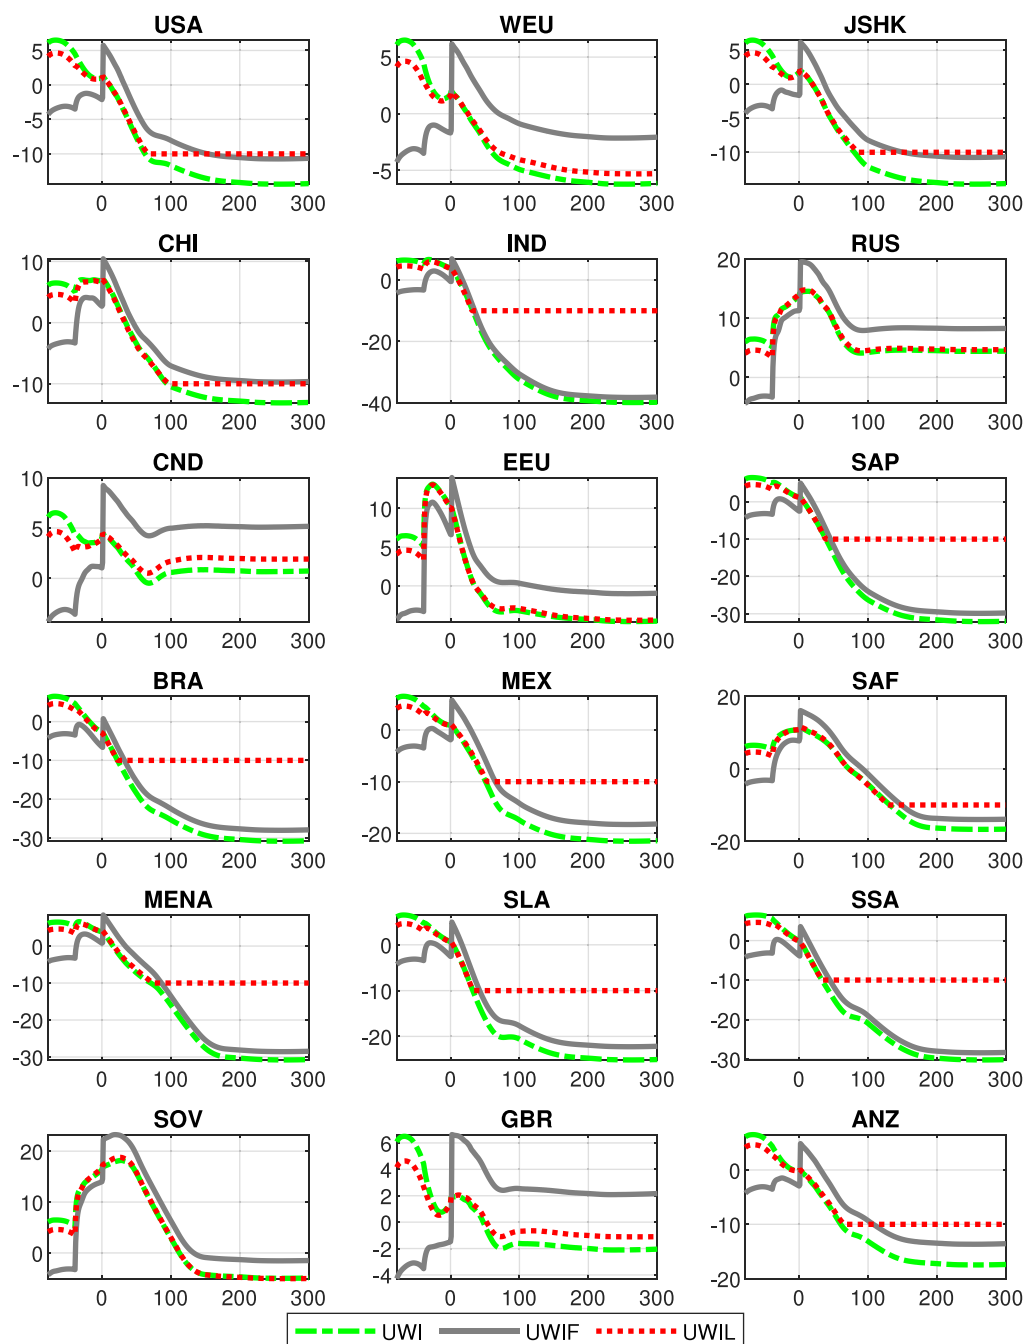

Fig. 4. Net transfers (y-axis) as a share of the remaining or full lifetime consumption of the unborn (x-axis) in the 6x case. Year 0 on the x-axis is 2017. The x-axis references the cohort year of birth.

used in producing green energy.²³ However, as indicated in Fig. 7, there are large welfare gains for many region-specific future generations to be shared. The green, dashed-dotted line shows the uniform 4.3 percent UWI gain.

Fig. 7's remarkable finding is the closeness of the green and red dotted lines for regions that never hit the 10 percent limit. The dotted red line is slightly lower – 4.0 percent – under UWIL policy for generations in regions that do not exceed the limit. Other generations in other regions enjoy much larger welfare gains under UWI. For example, the gain for future Indians peaks around

²³ Recall, all carbon taxes are lump-sum rebated to the dirty-energy companies, i.e., to their owners, namely initial generations.

Fig. 5. Global carbon tax under different scenarios, in \$ per ton of CO₂, assuming the 6x damage specification. The year 0 on the x-axis represents 2017.

35 percent (cf. the red-dotted UWIL line). For future citizens of SAP, BRA, SSA, and MENA, the peak gain exceeds 20 percent (cf. the red-dotted UWIL line). Even future Americans enjoy far higher welfare gains; that is, the dotted red curve is roughly twice the dotted green curve UWI level from roughly year 150 on.

The moral here is that by implementing UWIL policy and, thereby, giving up a very small portion of their UWI gain, early generations can dramatically improve the welfare of future generations. Moreover, they can substantially enhance policy compliance as no generation in any region is asked to pay more than 10 percent of their lifetime consumption in net taxes. Paying this net tax will deliver net welfare gains in regions like India that are an order of magnitude larger than their required 10 percent net tax.

5.2.2. Reductions in emissions, temperature, and damages

We now consider the effects of UWIL and UWIF carbon tax policies on emissions and damages. We focus again on the 6x damage specification. The results for the 4x damage case are similar. With even lower damages, optimal carbon taxes are low and, consequently, matter little. Fig. 6 shows the path of emissions under our alternative policies. Remarkably, the reduction of emissions is substantial and essentially identical whether or not the policy incorporates the sharing of net welfare gains across region-specific generations.

The emissions reductions are similar and decrease quickly, regardless of the transfer schemes. As Figs. 14, 15, and 16 in Appendix A.2 detail, the different regions stop using dirty energy at very different dates. China, for instance, stops using all fossil fuels in roughly 20 years compared to 75 years under BAU. Furthermore, Russia stops emitting carbon roughly 80 years earlier than in BAU due to the carbon policy. The quick substitution of clean energy, gas, and oil for coal may seem unrealistic. However, such a substitution is arguably already underway in China and other regions, which are rapidly building nuclear power plants while shutting down coal plants.²⁴ As the row “Max. global temperature rise” in Table 6 shows that taxing carbon at its marginal social cost dramatically limits the increase in temperature. This is true whether or not compensation is provided. Indeed, the rise in global temperature stays within or near the 2.0-degree limit set in the Paris Agreement. Fig. 8 shows, for 6x damage specification, that carbon taxation, again, no matter the compensation scheme, lowers all regions’ temperature paths by roughly the same amount.

Fig. 9 shows the extremely heterogeneous nature of climate damages across regions, ranging from huge ones in India to negative ones in Russia and Canada. In addition, the figure also displays the significant reduction in economic damages caused by the optimal taxes: The green, optimal 6x UWI carbon tax damage curves lie below the black BAU curves for all regions but CND and RUS. The different levels of the two curves show that carbon taxation can dramatically reduce regional climate damage; the reduction is almost 50 percent for almost all regions. For example, in ANZ, maximal damages drop from 20 percent to just above 10 percent, most notably in China, and the US damages drop from above 16 percent to around 8 percent of GDP.

²⁴ See, e.g., <https://cnpp.iaea.org/countryprofiles/China/China.htm>, <https://www.forbes.com/sites/jamesconca/2021/04/23/china-will-lead-the-world-in-nuclear-energy-along-with-all-other-energy-sources-sooner-than-you-think>, <https://world-nuclear-news.org/Articles/China-starts-construction-of-demonstration-SMR>, or <https://www.bbc.com/news/uk-england-somerset-58724732>.

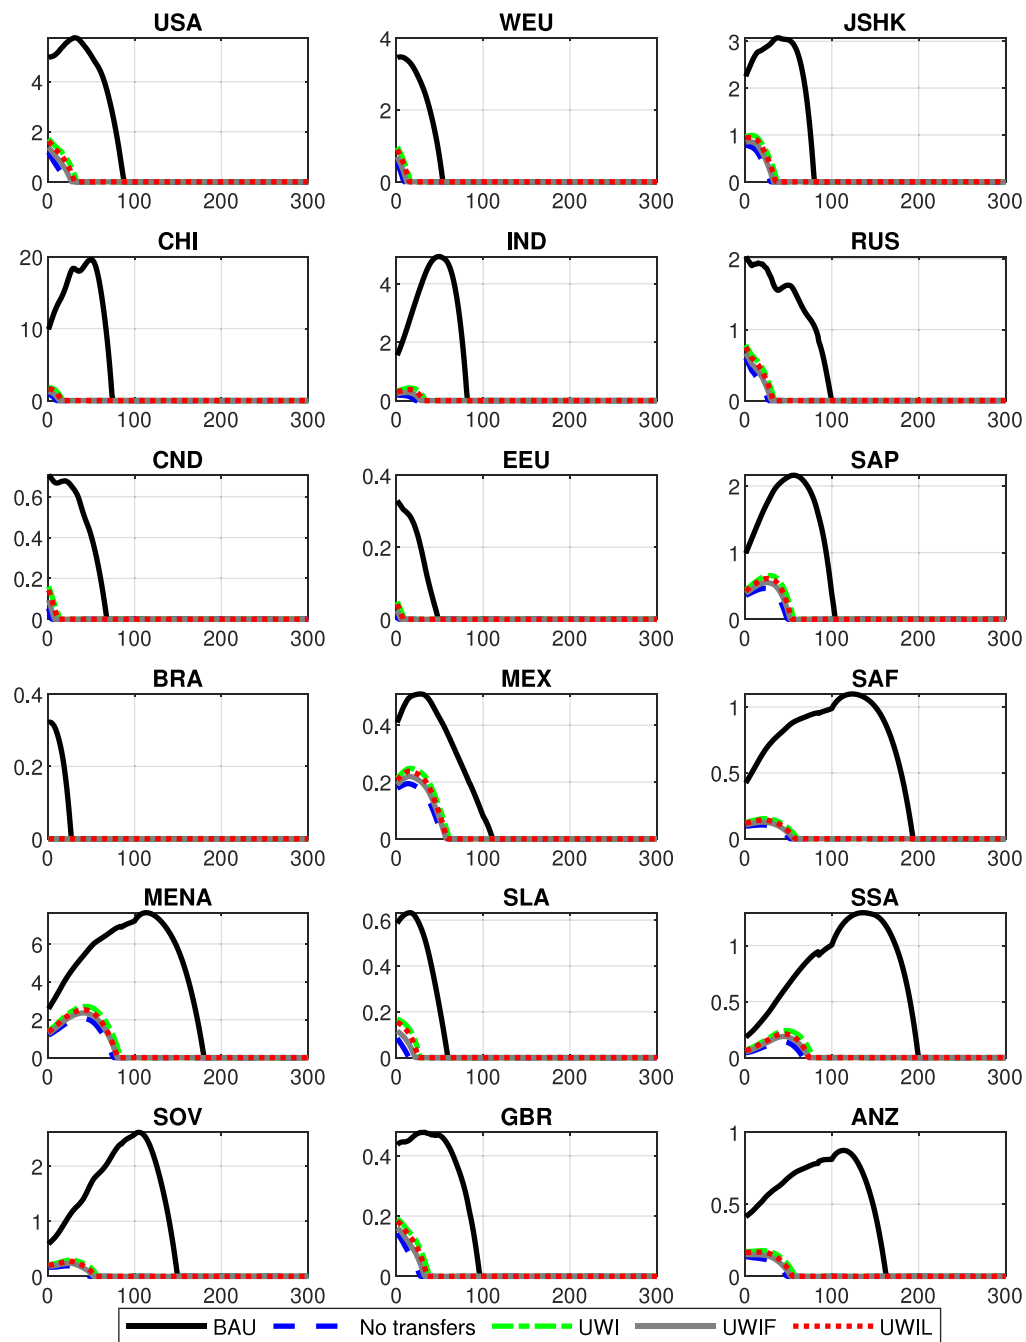

Fig. 6. Total CO2 emissions (y-axis) for the 6x damage specification as a function of years, and our different policies (measured in GtCO2; year 0 on the x-axis is 2017).

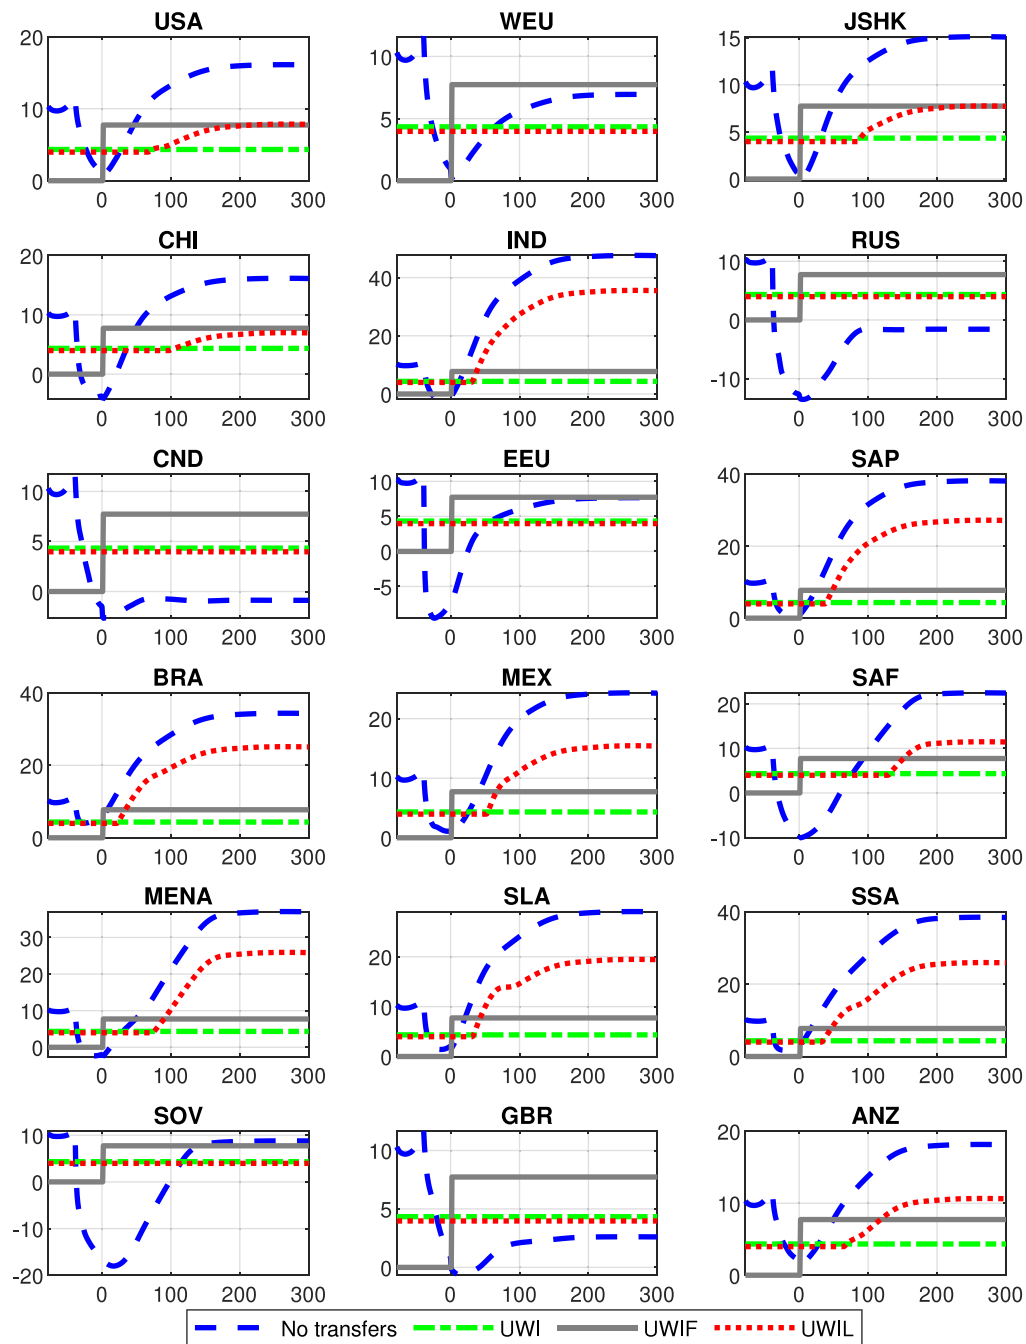

Fig. 7. Welfare gains (y-axis), measured as compensating consumption differentials in percentages as a function of years and our different policies; year 0 on the x-axis is 2017. The x-axis references the year of birth for the 6x damage specification.

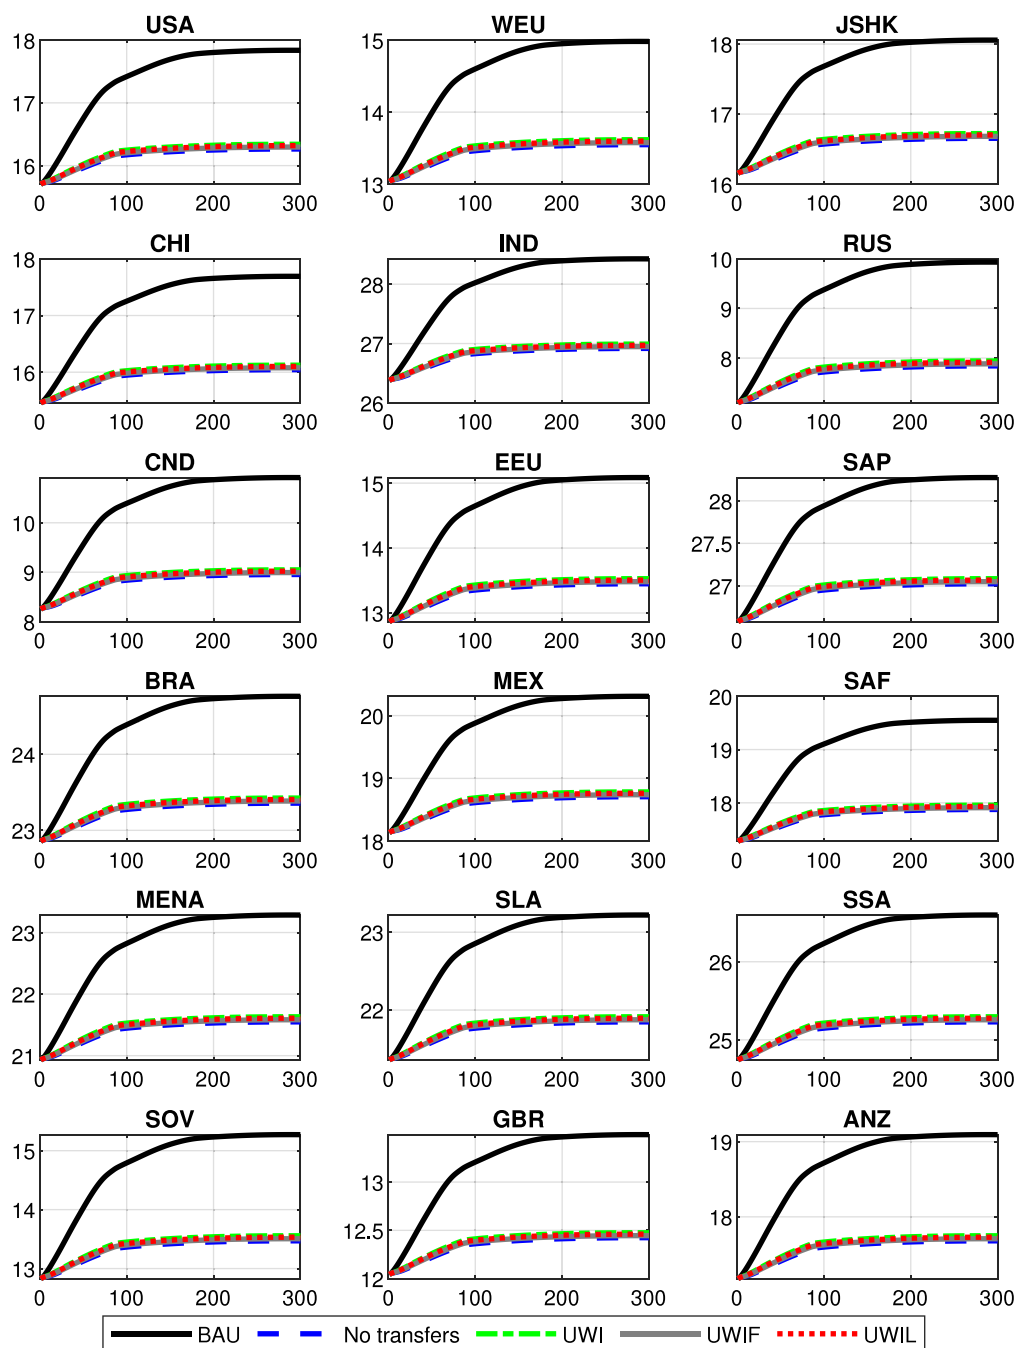

Fig. 8. Regional temperature (y-axis) in the 6x case (measured in °C) as a function of years and our different policies; year 0 on the x-axis is 2017.

5.2.3. Net transfers

Optimal carbon taxes, as illustrated in Fig. 5, are substantial in magnitude and have significant economic implications. Specifically, they can lead to a marked reduction in the consumption of fossil fuels, thereby yielding long-term benefits for future generations. However, carbon taxes can require compensating current generations to ensure that they do not incur welfare losses. Fig. 4 compares paths of net transfers paid to successive cohorts by year of birth. The horizontal axis specifies the cohort year of birth.²⁵

²⁵ For example, a value of -10 on the MENA chart's horizontal axis references the age-30 MENA generation in 2017.

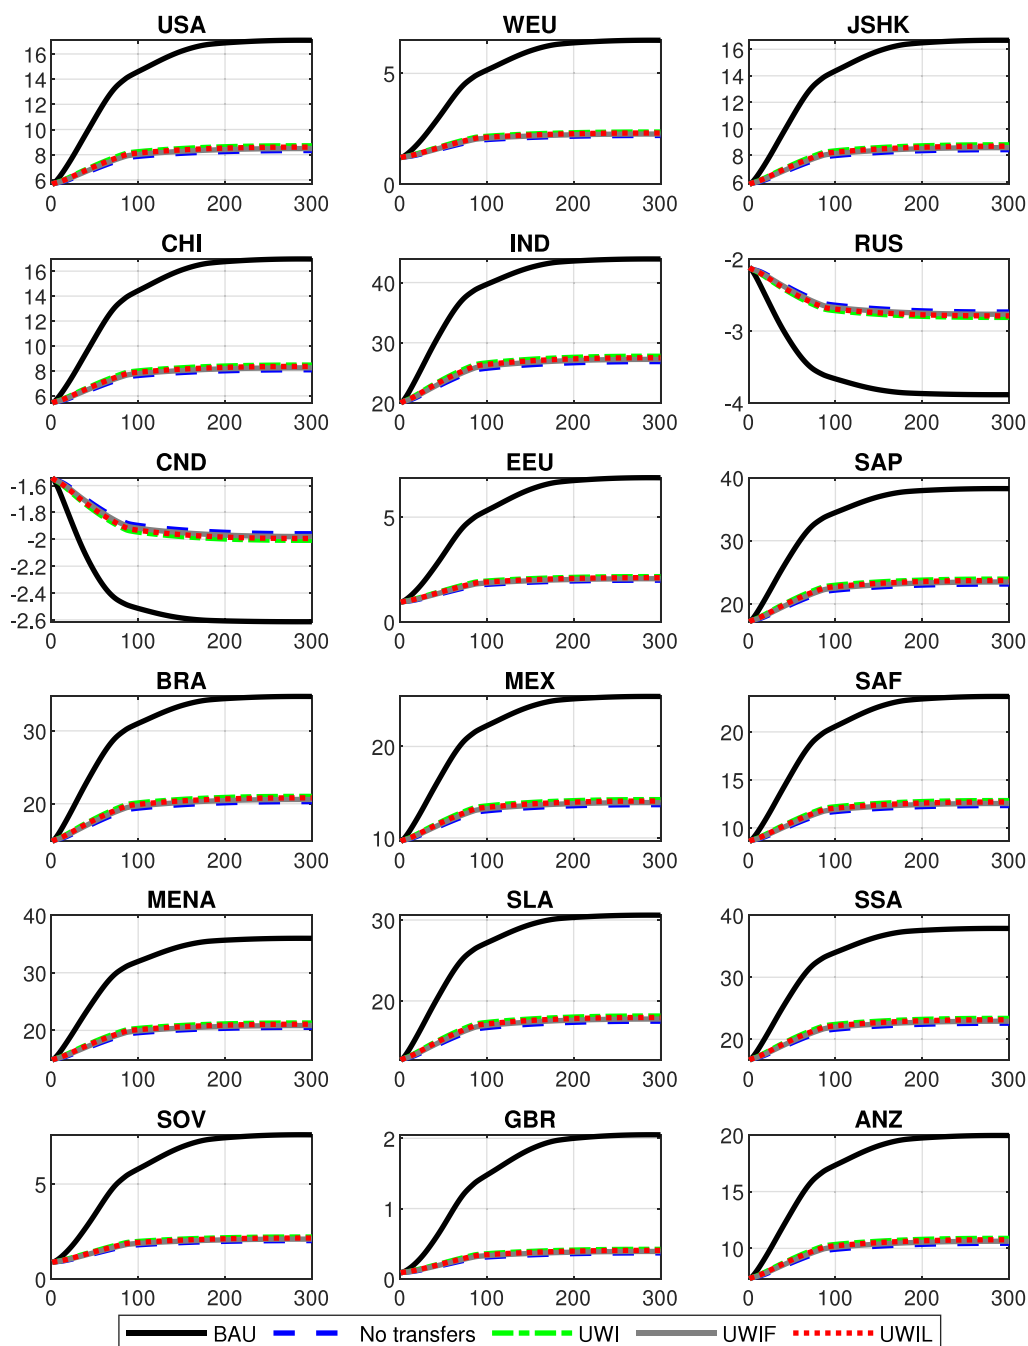

Fig. 9. Regional damages (y-axis) in the 6x damage specification (measured as a percent of regional GDP as a function of years and our different policies; year 0 on the x-axis is 2017).

The green dashed line references the UWI policy. The net UWI transfers turn sharply negative for future generations in regions like India, where climate change, absent mitigation, would take the largest toll. For example, Indians born in 200 years would be required under the UWI policy to surrender around 40 percent of their consumption to help service outstanding carbon-policy debt. Other regions with similarly large transfers include BRA, SAP, MENA, SLA, and SSA, whose future generations all need to transfer more than 20 percent of their consumption to other regions and generations.

At first consideration, this sounds extremely onerous and unfair. After all, India is among the world's poorer regions. Why should it be effectively required to subsidize far richer regions, like the US (whose long-run net tax is much smaller), which are causing a much larger share of the global externality? The answer is that adhering to this policy will benefit Indians, including all future

Table 7
Regional GDP as a share of world GDP in the 6x damage scenario.

Indians, to the same degree as it benefits those in the wealthiest regions. It is important to bear in mind that, thanks to the global carbon tax, future Indians will be paying a high net tax rate on a far larger level of consumption than would otherwise be the case. While *fairness* is not the issue, the UWI policy is unfortunately extremely unlikely to succeed. While future Indians today would agree on a contract that costs them 30 percent of lifetime consumption in exchange for optimal carbon taxes, come the year 2120, young Indians have absolutely no incentives to keep the contract. The vast literature on sovereign debt (see, e.g., [Eaton and Fernandez \(1995\)](#), [Cole and Kehoe \(2000\)](#), [Arellano \(2008\)](#)) and the vast number of cases of sovereign default clearly shows that the enormous debt levels required by our UWI policy in the 6x case are not sustainable.

One option is to allocate all efficiency gains from carbon taxation to future generations. But as [Fig. 4](#) and [Table 6](#) indicate, this makes essentially no difference to the high net taxes levied on future generations in those low-income regions hardest hit by climate change. Therefore, we consider our UWIL policy with its 10 percent net tax cap. The red dotted line shows transfer payments for this almost uniformly welfare-improving policy, which, arguably, has the greatest chance of political support from both current and future generations.

Surprisingly, although maximal transfers under the UWIL policy are much smaller than under the UWI policy, the welfare gains guaranteed for all generations and regions are almost as large. As depicted in [Fig. 6](#), all generations in all regions gain at least 4.0 percent (as opposed to 4.3 percent in the full UWI case). Naturally, future generations in regions hit hardest by climate change gain much more, with those in India gaining almost 40 percent (see [Fig. 7](#)). Since overall transfers are smaller than in the UWI case, the increase in the interest rate is also less pronounced, and hence optimal taxes are higher than in UWI, as can be seen in [Fig. 5](#).

5.2.4. Carbon policy and the future of economic power

This section considers whether carbon tax policy matters for the evolution of global economic power. [Table 7](#) examines this question for the 6x damage scenario. The answer is, perhaps. First, China is projected to eclipse the US economically with or without a carbon policy. In 2100, the US accounts for only 15.5 percent of global output compared with 25.0 percent in 2017. In contrast, China's share of world output grows from 15.6 percent in 2017 to 32.6 percent in 2100. However, the end of the US economic hegemony and the path to that end is essentially independent of carbon damage and carbon policy. This reflects the roughly equal proportionate climate damages, as a share of GDP, experienced through time by both the US and China (cf. [Table 5](#)). By 2100, the US is in third place in terms of the share of global GDP with only 15.5 percent of world output. This share is less than the 19.5 percent combined WEU and UK global GDP share.

Absent carbon policy, WEU's global GDP share, which is 3 percentage points less than the US share in 2017, surpasses the US share by almost 1.5 percentage points by the century's end. This gap drops to roughly half with carbon policy and reflects the relative importance of carbon policy to the US compared to Western Europe, indicated in [Table 7](#). India, which stands to lose the most from climate change, is another example of carbon policy's potentially significant, if hardly overwhelming, impact on the share of global GDP. In 2100, India's share of world output is 6.43 percent with UWI policy, but 5.38 percent without.

5.3. Infinite coal reserves and imperfect substitutability between green and dirty energy

This section considers the sensitivity of our results to alternative assumptions. The first concerns the supply of coal. We have assumed that coal reserves are finite and extractable at rising marginal costs. Suppose we follow [Golosov et al. \(2014\)](#) and treat coal reserves as infinite and available at constant marginal cost. [Fig. 10](#) compares the two cases with the solid black line reflecting our baseline and the solid gray line reflecting our alternative assumptions. Both scenarios assume perfect substitutability between dirty and clean energy.

As expected, the BAU infinite coal reserves scenario shows significantly higher coal usage, particularly during years 50 through 100. This increases carbon damages between years 75 and 300 by an additional 2.8% of global GDP. However, optimal policy is not invariant to assumptions about coal's supply. Optimal policy simply adjusts to our alternative conditions effecting a sharp reduction in coal use notwithstanding its perfectly elastic supply. Indeed, the use of coal under optimal UWI policy differs little in the two cases. Interestingly, the UWI gain in the infinite reserve scenario is 5.5% versus 4.3% in the baseline scenario. Since damages under BAU are higher when coal supply is in infinite supply, the carbon externality is larger. This implies a larger proportional payoff from mitigating carbon emissions. Optimal tax trajectories are very close to one another in the medium term and diverge substantially in the long term. Surprisingly, in scenarios with high emissions and larger long-run damages, the optimal tax is lower because the marginal damage from an additional unit of emissions is lower. The optimal tax in the first period is reduced to \$83.6 per ton of CO₂ compared to \$87.5 per ton in the baseline specification, and over the 100-year horizon, the optimal tax decreases to \$448 per ton compared to \$543 per ton in the baseline.

A different sensitivity question concerns the substitutability of clean for dirty energy.²⁶ Recall that our baseline model assumes the two types of energy are perfect substitutes. However, commercial jets cannot yet fly on batteries and will not likely do so in the near term. On the other hand, within a few decades, hydrogen or other clean jet fuel may be ubiquitous. Moreover, increasing the substitutability of clean for dirty energy can proceed through a different channel, namely carbon removal. Improvement in such technology could render all dirty energy clean (see, e.g., Fuss et al. (2020) for an analysis of the role of carbon capture in achieving net zero emissions). In this case, substitutability would obviously be perfect.

How sensitive are our results to assuming that clean energy can immediately perfectly substitute for dirty energy? As indicated, we address by considering gradual transitions from imperfect to perfect substitutability. Specifically, we assume that the final energy input used to produce output is, as indicated in Eq. (46), CES in clean and dirty energy with their elasticity of substitution, \tilde{u}_t , rising at different rates over the next three centuries. After year 300, we set \tilde{u}_t to infinity, i.e., we assume perfect substitutability.

$$E_{z,t} = \left(\kappa_{z,S}^{\frac{1}{\tilde{u}_t}} S_{z,t}^{\frac{\tilde{u}_t-1}{\tilde{u}_t}} + (1 - \kappa_{z,S})^{\frac{1}{\tilde{u}_t}} (E_{z,t}^D)^{\frac{\tilde{u}_t-1}{\tilde{u}_t}} \right)^{\frac{\tilde{u}_t}{\tilde{u}_t-1}}, \quad (46)$$

We consider three cases, each under the assumption that coal is in infinitely elastic supply. In the first, labeled high substitution, we let \tilde{u}_t rise linearly from 2 to 31.9 in 0.1 increments the 300 years. This case is denoted by blue dashed lines in Fig. 10. In the second case, medium substitution, referenced by green dashed lines, \tilde{u}_t equals 2 for 50 years and then rises linearly from 2 to 27 over the next 250 years. In the third case, low substitution — the red lines, \tilde{u}_t equals 2 during the first 100 years and rises linearly from 2 to 22 over the next 200 years.

As expected, slower green-for-dirty substitutability leads to significantly higher dirty energy usage in the short and medium terms. This is particularly true for coal. Slower substitutability entails larger carbon damages. In the low-substitution case, they are roughly 12 percent greater at the end of this century and for several centuries thereafter. Interestingly, in all scenarios with imperfect substitution between clean and dirty energy sources, the UWI gain is roughly 4.8 percent of GDP. Thus, the assumption of infinite coal reserves increases the gains from climate policy, while imperfect substitutability reduces them. The trajectory of the optimal tax in the case of low substitutability turns out to be the lowest. The optimal tax in the first period turns out to be \$81.5 per ton in the first period and \$272 per ton after 100 years.

5.4. Inefficient policy

Pareto-optimal taxes require large inter-regional and intergenerational transfers. But absent the transfers required to effect a Pareto improvement, initial generations will suffer significant losses. Unfortunately, it is far from clear how to enforce such transfers, which require redistributing across regions through time (see, e.g., Hassler et al. (2020)). Climate change action is, after all, a classic free-rider problem. If, say, a few relatively small regions choose not to participate in collective carbon tax policy, the overall reduction in CO₂ emissions and future damages will be largely unaffected. Therefore, the region has no incentive to participate even if it expects significant future damages in the BAU scenario.

The subsequent Sections 5.4.1 and 5.4.2 discuss how our model's outcomes differ if global participation does not materialize, leaving single regions or subsets of regions to implement their own UWI carbon policy.

5.4.1. Partial international participation

In considering carbon tax policy in a given subset of regions (i.e., climate clubs), we tax the use of dirty energy in all subset regions but now redistribute all carbon tax revenues to households in participating regions in proportion to their populations. Fig. 11 shows the effect of a regional \$100 carbon tax on global emissions. In addition to a global tax, we also consider a tax only in CHI, JSHK, GRB, WEU, and the US and taxes only in the US, only in CHI, only in JSHK, and only in WEU and GBR.

As the figure shows, taxes levied in only a single region have limited effects, even if that region is China. A \$100 Chinese-only carbon tax, with a 1.5 percent growth rate, lowers initial global emissions by roughly one-sixth. In contrast, a \$100 carbon tax, growing at 1.5 percent annually but levied only in the US, only in Western Europe, or only in JSHK, has almost no effect on global emissions. The larger Chinese impact reflects China's coal-intensive technology for producing dirty energy.

²⁶ As highlighted by Gross (2023), decarbonizing certain industrial processes, which necessitate the use of extremely high temperatures, presents significant challenges.

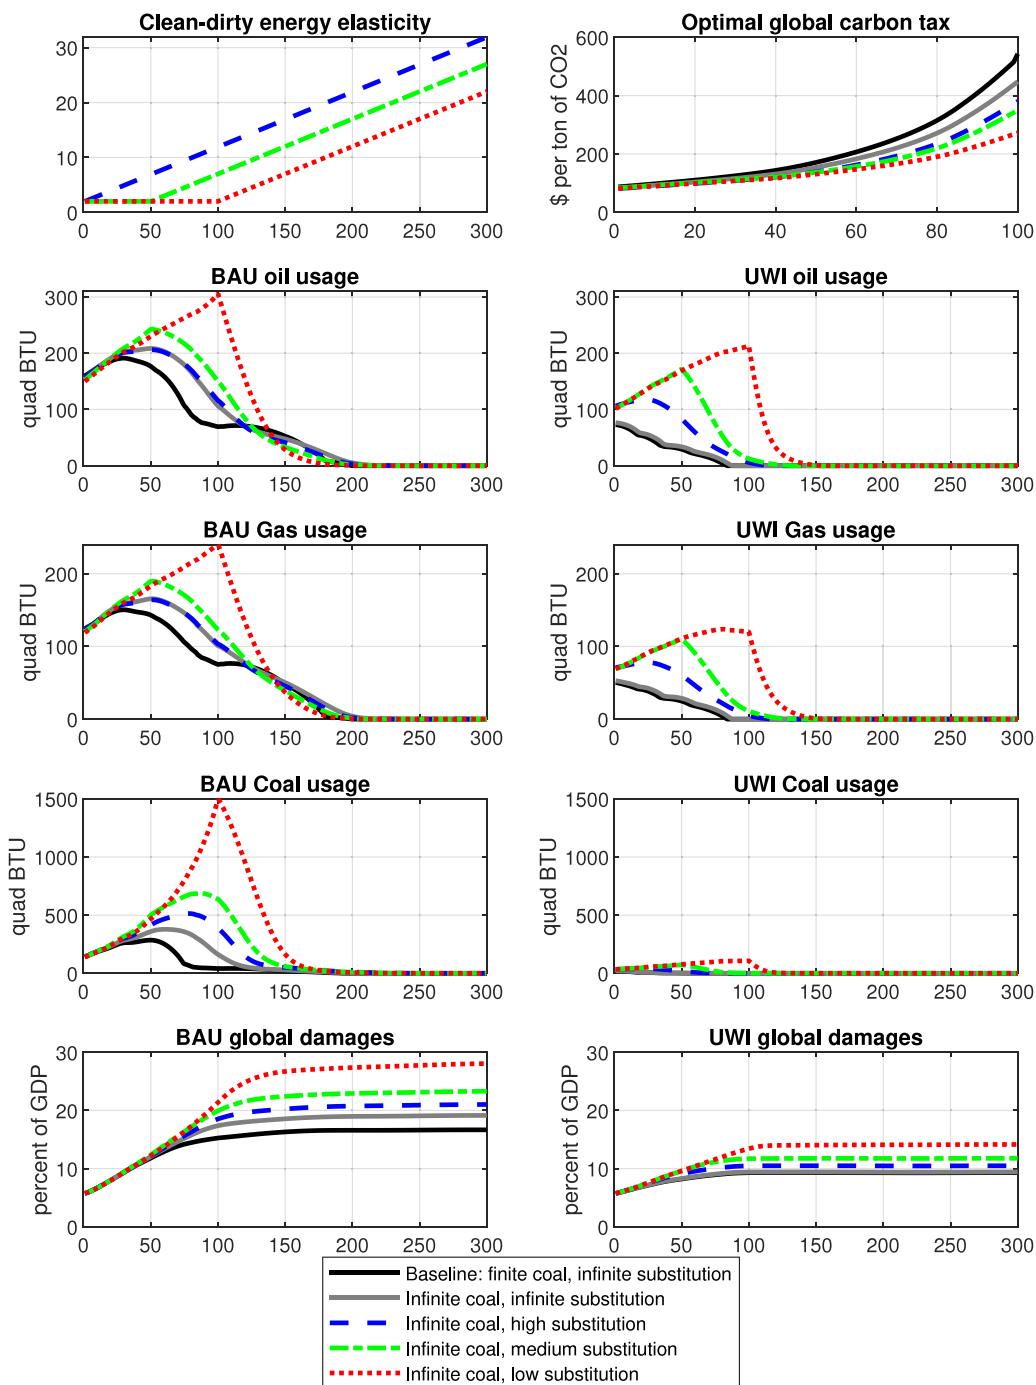

Fig. 10. Key variables for the 6x damage scenario case when dirty and clean energy are imperfect substitutes in the short and medium run as a function of years and our different policies; year 0 on the x-axis is 2017. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Given the relatively small impact of a large regional tax on emissions and warming, the issue of partial participation is clearly problematic. If one hopes for regional welfare gains from optimal regional taxes and transfers, one is easily disappointed. Tables 9 and 10 in Appendix A.2 illustrate the problem by reporting the regional SCC for different regions and different years. For the 6x damage scenario BAU case, this regional SCC is only significant in China and the US. Despite the fact that damages are projected to be very large in regions like India and Brazil, the 2017 SCC for India is only about \$ 10.58, and for Brazil, only \$ 3.12. The global SCC, in this case, is \$ 111.69. As one would expect from these numbers, it turns out that only one partial coalition – all regions apart

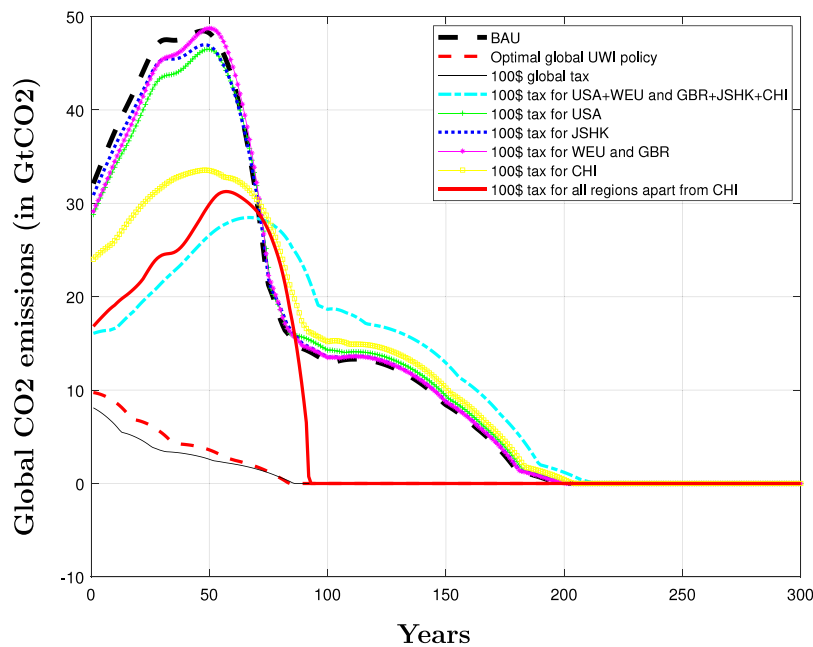

Fig. 11. Global CO₂ emissions (absent of land emissions, and measured in GtCO₂) in the 6x damage scenario under alternative coalitions as a function of years (starting in 2017).

from China – appears capable of producing a positive welfare gain for its members. For example, a \$100 carbon tax, approximately equal to the global SCC, levied by all regions apart from China and grown annually at 1.5 percent produces a 1.5 percent UWI gain for coalition members.

We also considered coalitions that tax themselves not based on the global SCC but only on their collective local SCC. They redistribute among themselves to achieve a uniform welfare gain among all members. In this case, there are three coalitions with positive welfare gains: UWI gains equal to 1.6 percent for all regions apart from CHI. The equal 0.9 percent for a coalition consisting of the US, WEU, GBR, JSHK, and CHI. They equal only 0.3 percent for a coalition consisting solely of CHI.

The inability of subsets of regions to get close to the joint global optimum reflects, in large part, general equilibrium effects. When one region or a subset of regions imposes carbon taxes, they drive down the price of dirty energy. This, in turn, leads non-participating regions to increase their use of fossil fuels. For example, a \$100 Chinese-only carbon tax growing at 1.5 percent real leads other regions to increase their collective year-2250 emissions by 17 percent.

If all regions apart from China do the same, China will increase its cumulative emissions by 78 percent. If the USA, WEU, GBR, JSHK, and China impose a \$100 carbon tax, with a 1.5 percent growth rate, other regions collectively increase their cumulative CO₂ emissions by 43 percent. This Black Paradox resembles the “Green Paradox” discussed below in Section 5.4.2. The bottom line is clear. Carbon taxation needs to be global to be effective.

5.4.2. Delaying carbon taxation and the Green Paradox

A major concern with carbon policy is its timing. As Sinn (1982) points out, announcing the implementation of a carbon tax in advance will alert dirty-energy producers to “use it or lose it”. Indeed, Kotlikoff et al. (2016) suggest the Paris Accord may have worsened climate change via its Green Paradox repercussions. Of course, speeding up the burning of fossil fuels will accelerate climate change relative to BAU — hence the term *Green Paradox*. The problem is lessened when, as in our model, there is costly dirty-energy extraction. However, a delay in our model also comes at a cost. Indeed, postponing the implementation of the optimal UWI tax until 2040, taking into account its growth, reduces the 1x damage specification case UWI gains from 0.6 to 0.5 percent. In the 2x damage specification case, the UWI gains drop from 1.4 to 1.0 percent. In the 4x case, the decline in gains is from 3.0 to 2.0 percent. Furthermore, in the 6x case, the reduction is from 4.3 to 2.8 percent. Note that delay reduces maximum UWI gains and increases emissions over the entire transition path, not starting when the policy begins.

What if all regions but China immediately adopt a carbon tax, but China waits 20 years?²⁷ This lowers the UWI gain from 4.3 percent to 3.8 percent in the 6x damage specification case. In the 4x case, China’s delayed participation reduces the UWI gain from 3.0 percent to 2.7 percent. In contrast, in the 2x and 1x cases, the UWI gains are virtually unaffected by a Chinese delay in joining all other regions in taxing carbon.

²⁷ Chinese generations born after that receive transfers to ensure they get the same uniform welfare gains as the rest of the world.

6. Conclusion

Climate policy is generally viewed as a zero-sum game pitting the future against current generations and regions that benefit from climate change against regions that do not. Our study suggests that, absent policy, potential losses to future generations are substantial. Indeed, absent policy, climate change produces peak GDP regional losses under our “high damage scenario”, ranging as high as 43.9 percent in the case of India. They exceed 30 percent for SSA, SLA, MENA, BRA, and SAP. For the US, losses peak at 17.1 percent. In contrast, for Russia and Canada, climate change is good news. Under BAU, Russia’s and Canada’s peak output gains are 3.9 percent and 2.6 percent, respectively.

These BAU reductions in output take decades, but not millennia. India’s peak loss of over two-fifths of its output occurs in 2200. Since fossil fuels eventually go economically extinct, the BAU growth impact is “temporary” if our time frame is millennia and if long-run TFP growth remains positive. But this does not mean that it has small effects on welfare. India’s current per capita GDP is just over \$7,000. An immediate 40-plus percent reduction in India’s GDP would spell massive starvation on that impoverished continent. The fact that, for India, primarily externally generated climate change will extract its maximum penalty in 200 years is hardly comforting, neither for its inhabitants nor for the rest of the world.

Fortunately, there is a simple, mutually beneficial solution to this seemingly insurmountable problem. We show that a compensatory carbon tax policy can achieve a win-win for all cohorts regardless of their place or time of birth. Indeed, carbon taxation coupled with region- and generation-specific positive or negative transfers can achieve a uniform welfare gain, that is, an identical percentage improvement in economic well-being for all. Our optimal UWI gain is 4.3 percent, measured as a consumption equivalent. This policy is effected by (a) levying an annual global carbon tax equal to the contemporaneous SCC, (b) making transfers to cohorts that would otherwise gain less than 4.3 percent, and (c) taxing cohorts that would otherwise gain more than 4.3 percent. Those receiving transfers include both Russians and Canadians, for whom climate change represents a positive externality, and early cohorts in most regions, that is, cohorts born too soon to benefit from climate change’s mitigation, yet stuck paying higher energy prices. Those paying taxes are future generations in regions otherwise harmed, and potentially greatly so, by climate change.

However, the redistributive aspect of UWI policy may be unenforceable due to the very high taxes required of future cohorts in many regions. To mitigate this time consistency problem, we explored a UWIF policy, that is, a UWI policy, but with the uniform welfare gain restricted to future generations. Current generations are left with their BAU levels of utility. The UWIF policy provides all future generations with a 7.7 percent welfare gain. Furthermore, it limits the taxes they face to compensate prior generations. However, their projected tax bill remains extremely high, especially for Indians. Indians born in 2200, for example, pay the equivalent of 38.2 percent of lifetime consumption in taxes. This is only slightly lower than the 39.9 percent under UWI.

Our UWIL policy significantly lessens the time-consistency problem. It provides a uniform welfare gain to all cohorts in all regions apart from cohorts who would otherwise pay taxes exceeding 10 percent of their lifetime consumption. Taxes on such cohorts are limited to this 10 percent level, meaning they enjoy a higher welfare gain than under UWI policy. Importantly, UWIL still delivers major welfare gains, namely 4.0 percent for all cohorts under the tax limit and far higher for cohorts at the tax limit. For example, Indians born in the long run experience a 35.6 percent welfare gain, which is dramatically higher than the gains under UWI or UWIF policy.

For our high-damage case, the UWIL carbon tax starts at \$ 91.4 per ton of CO₂, rising, in real terms, at roughly 1.5 percent per year. This policy dramatically reduces global and region-specific climate damage. It also materially shortens the duration of fossil fuel usage by approximately 130 years. Rather than increasing by as much as 3.7 degrees Celsius under BAU, the peak temperature rise under UWIL policy is 2.1 degrees. Peak global damages under UWIL are 9.2 percent of the planet’s GDP. For India, the worst-hit region under BAU, damages peak at 27.5 percent of GDP under UWIL versus 43.9 percent under BAU.

Our optimal path of carbon taxation, as well as the associated UWI gain, is little affected by assuming less than perfect substitutability in the short- and medium-term of clean for dirty energy. Considering, as we do, a nine-decade transformation of technology to the point that clean and dirty energy are perfect substitutes does lead to significantly greater use of dirty energy, particularly coal. But the dirty-energy end dates, beyond which neither coal, oil, or gas are used, are little affected.

A.1. Calibration

Table 8 reports GDP, energy consumption, and CO2 emissions by region relative to the US. Fig. 12 reports UN-projected demographics in the 18 regions. Projected population declines in almost all regions, with the only exceptions being the US, CND, SSA, and ANZ; it is projected to increase over the next 100 years and then remain constant. The wiggles in some of these graphs come directly from the UN data. Fig. 13 compares aggregate BAU damages resulting from our 1x damage specification of the damage function to aggregate damages predicted by DICE (Nordhaus, 2017). It can be seen that predicted damages are similar in both specifications.

A.2. Additional findings

Tables 9 and 10 depict the region-specific SCC for the 6x specification of the damage function. The optimal case refers to the UWI policy. Clearly, the SCC is high for regions with high total GDP, notably CHI and USA. Note that in the optimal cases, the tax on carbon equals the SCC.

Figs. 14, 15, and 16 depict projected oil, gas, and coal use both under BAU and under the 6x UWI optimal policy. The dramatic effect of the taxes on coal use is notable.

A.3. Computational details

This section details our solution algorithm, which recursively solves a series of simple one-period problems.²⁸ We also use an iterative procedure to find the optimal carbon tax path, updating each period's carbon tax to that period's SCC in each iteration.

We first describe our five-step algorithm conditional on a given tax path.

- Step 1.1: Set a high value of \bar{t} , in our case, 1000, to provide sufficient time for atmospheric CO2 to stabilize, permitting the economy to reach its steady state. Also, guess the time paths of the aggregate capital stock, oil, coal, and gas reserves, and region-specific total factor productivities.
- Step 1.2: Next, use backward induction for $t = \bar{t} - 1, \dots, 1$ to solve the nonlinear system of equations (1)–(9), (11)–(16), (24)–(26), and (32), (34), (35). Their solutions provide region-specific final output paths, $Y_{z,t}$, region-specific final-output factor demands for capital, $K_{z,y,t}$, labor, $L_{z,y,t}$, and energy, $E_{z,t}$, the world interest-rate path, r_t , region-specific paths of wages, $w_{z,t}$, region-specific paths of energy prices, $p_{z,t}$, region-specific clean-energy output paths, $S_{z,t}$, region-specific clean-energy factor-demand paths for capital, $K_{z,s,t}$, and labor, $L_{z,s,t}$, region-specific land rental price paths, $n_{z,t}$, region-specific usage paths of dirty energy, $E_{z,t}^D$, oil, $O_{z,t}$, gas, $G_{z,t}$, and coal, $C_{z,t}$, region-specific dirty energy prices, $p_{z,t}^D$, regions-specific paths of the Lagrange multiplier governing dirty energy usage, $\chi_{z,t}$, paths of

²⁸ For further implementation details, please refer to the repository hosted at the following URL: https://github.com/ClimateChangeEcon/Can_Todays_and_Tomorrows_World_Uniformly_Gain_from_Carbon_Taxation, which contains all replication codes.

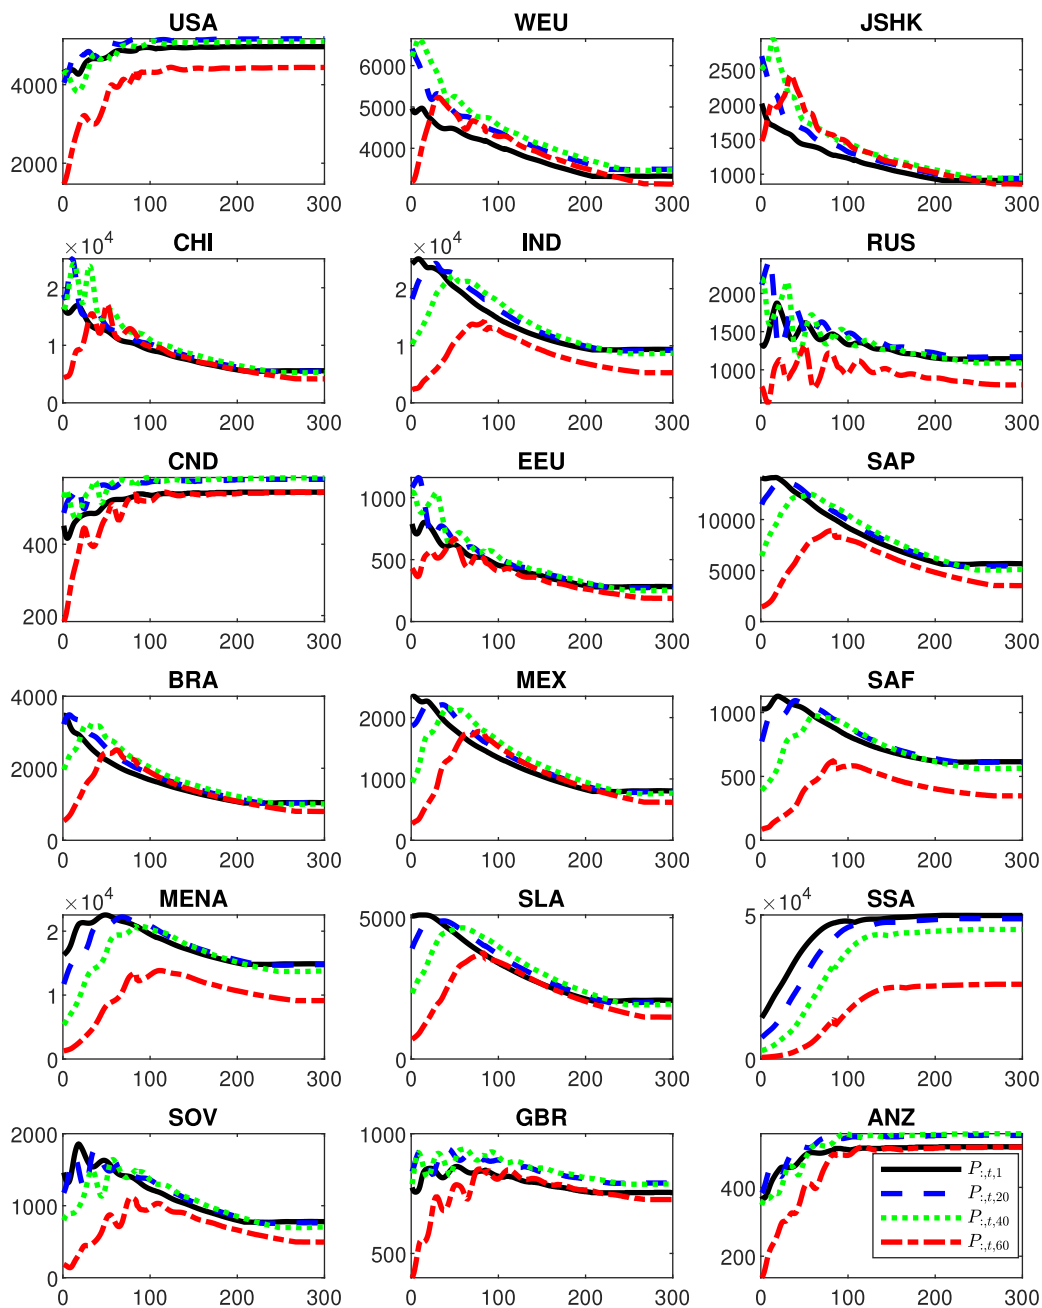

Fig. 12. On the y-axis, we display the projected population (in thousands) of specified age groups as a function of years.

Fig. 13. Comparing the “DICE” and “Krusell-Smith”(cf. Eq. (44)) global damages as a share of global GDP (measured in %) by year (starting 2017).

global extraction of oil, O_t , gas, G_t , and coal, C_t , paths of global prices for oil, p_t^O , gas, p_t^G , and coal, p_t^C , the path of Lagrange multipliers governing extraction of the dirty-energy reserves (21), ℓ_t^O , ℓ_t^G , ℓ_t^C , paths of Lagrange multipliers restricting dirty-energy extraction to be positive (23), μ_t^O , μ_t^G , μ_t^C with given regional productivity in final output, $A_{z,t}$, and clean energy, $B_{z,t}$, production sectors, regional land supply, $H_{z,t}$, regional labor supply, $L_{z,t}$, world capital supply, K_t , reserves of oil, R_t^O , gas, R_t^G , and coal, R_t^C , and next-period Lagrange multipliers for dirty energy reserves extraction dynamics (21), ℓ_{t+1}^O , ℓ_{t+1}^G , ℓ_{t+1}^C .

The Lagrange multipliers, ψ_t^O , ψ_t^G and ψ_t^C , ensuring the non-negativity of dirty-energy reserves (see (22)), are never binding and, thus, set to zero. Finally, the terminal values of the Lagrange multipliers for dirty-energy reserves dynamics are set equal to zero, ℓ_t^O , ℓ_t^G , ℓ_t^C . Thus, for each point in time, t , we solve a system of 301 equations for 301 variables.

- Step 1.3) Use the above-referenced trial solution paths to determine the region-specific time paths of households' aggregate supplies of capital. From the paths of oil, gas, and coal extraction, we also determine the global time paths of dirty energy reserves, climate variables, damages, and region-specific productivity.
- Step 1.4) Update guessed time paths of the aggregate capital stock, oil, coal, and gas reserves, and region-specific productivity paths.
- Step 1.5) Iterate on steps 1.2–1.4 until convergence.

Next, consider solving the model for a given carbon tax path (the zero-tax scenario is equivalent to the BAU scenario) combined with the use of the Auerbach and Kotlikoff (1987) Lump-Sum Redistribution Authority (LSRA), which can implement pre-specified Pareto-efficient outcomes. We first use the LSRA by Auerbach and Kotlikoff (1987) to derive the largest UWI carbon tax policy, where welfare changes are measured as compensating consumption differentials, that is, λ .

- Step 2.1: Guess λ .
- Step 2.2: Given the guessed λ , iterate on steps 1.2–1.4, including updating transfers to ensure uniform welfare gains increase.
- Step 2.3: Calculate a present value of the transfers. If it is positive, decrease λ . If it is negative, increase λ .
- Step 2.4: Iterate on steps 2.2–2.3 until the present value of transfers approaches zero.

We determine the optimal global carbon tax rate path numerically as follows:
